Western Ophthalmological Association.—The following officers were elected at the sixth annual meeting of the Western Ophthalmologic and Oto-Laryngologic Association held in Cincinnati April 11th and 12th: Dr. C. R. Holmes, Cincinnati, O., President; Dr. W. L. Dayton, Lincoln, Neb., 1st Vice-President; Dr. J. O. Stillson, Indianapolis, Ind., 2d Vice-President; Dr. H. W. Loeb, St. Louis, Mo., 3d Vice-President; Dr. O. J. Stein, 100 State street, Chicago, Treasurer; Dr. William L. Ballenger, 100 State street, Chicago, Secretary.

At the meeting in Cincinnati the scientific program was of very high grade. Forty new members were elected. The next meeting will be held in Chicago, April 10, 11, and 12, 1902.

Dentists for the Army.—The Army bill of this year made provision for the first time for the care of soldiers' teeth by authorizing the appointment of dental surgeons by the Secretary of War on the recommendation of the Surgeon-General. These dental surgeons are to be in the proportion of one to every 1,000 men of the army, but are not to be more than thirty in all. That is, there ought to be seventy-five or more, but only thirty can be appointed. Contract dental surgeons are to have the pay of army contract surgeons, $150 a month and to have the same rights and duties as those "acting assistant surgeons." Contracts will be made with them for three years, terminable after investigation by the Commanding General of a department, or by the Surgeon-General, when he thinks it will be for the interests of the service. Dental surgeons are to be between the ages of twenty-four and forty, and are to pass a professional examination before a board of three examining dental surgeons. This board has been formed by the Secretary of War and contracts with some surgeons have been made, though no dental surgeons have yet been sent to army posts.

Roentgen Ray Institute.—At the Dermatological Clinic of the University of Berlin an institute for light treatment and for Roentgen-ray therapy has been opened under the directorship of Professor E. Lesser.

University of Havana.—Dr. Aristides Agramonte, formerly Chief of the Bacteriological Laboratory, has been appointed to the Chair of Bacteriology and Experimental Pathology in the Medical Faculty of the University of Havana, Cuba.

Suffolk District Medical Society.—At the last regular and annual meeting of this Society,

held at Boston April 27th, Dr. Franz Pfaff read a paper on the "Teaching of Therapeutics"; and before the Surgical Section Dr. C. L. Scudder read a paper on "Strangulation of the Testis by Torsion of the Cord"; Dr. J. W. Elliot, "Report on Two Cases of Strangulation of the Intestine by Bands"; Dr. F. G. Balch, "Report of a Case of Intussusception."

Obituary.—Dr. Ginlo Bizzozen of Turin, widely known as an investigator in histological and pathological lines, died April 8, 1901. He was born in Lombardy in 1846 and studied medicine in Pavia, Zürich and Berlin. In 1872 he was appointed Professor of Pathology in the University of Turin. His investigations on the blood, connective tissues, bone-marrow, lymph-nodes and dural tumors are classical. Many of the ablest investigators of the present time in Italy were his pupils, Golgi, Tizzoni, Foa, Canalis, Morpugo and others.

Dr. Richard C. Baker, of 75 Lee Avenue, Williamsburg, who was secretary of the Brooklyn Health Department under Mayors Chapin and Boody, died last week of tuberculosis, aged fifty years. Dr. Baker was born in Otsego and was graduated from the University of New York in 1874. He went to Williamsburg, where he built up a large practice and for many years was prominent in Democratic politics.

Dr. George Cogswell died at Haverhill, Mass., April 21st, aged ninety-three years.

OBITUARY.

WILLIAM HENRY DRAPER, M.D.

Dr. William H. Draper died Friday morning, April 6th, at his home. Pneumonia was the cause of death, but for more than a year past he has been in failing health. Dr. Draper was for many years one of the best known and most prominent physicians in New York. He was notably a general practitioner in medicine. Next to his standing as a general practitioner, Dr. Draper was a teacher of medicine. Hundreds of students listened to him and learned from him more than they were able to learn from any other instructors, not only because of what he taught—many taught as much—but owing to his way of teaching.

Dr. Draper was born in Brattleboro, Vt., on October 14, 1830, and came early to this city. He was a musician and he utilized his accomplishment as an aid in acquiring his education, serving as an organist in St. Thomas's Church when it was at Broadway and Houston Street, on the site now occupied by the cable building of the Metropolitan Street Railway Company. He studied at Columbia College, from which he was graduated in 1851. He was graduated in medicine from the College of Physicians and Surgeons in 1855, and in the same year received the degree of master of arts from Columbia. He went to Europe then and studied in Paris and London. Returning to this country, he was appointed in 1869 clinical professor of diseases of the skin at the College of Physicians and Surgeons. He was at that time regarded as a specialist in diseases of the skin, but that was as near as he came to being a specialist. He never took up a specialty as the term is understood by medical men nowadays. He retired from this professorship in 1879 and in the following year he was appointed professor of clinical medicine. He held this post until 1888, when he resigned and was appointed emeritus professor.

He was a trustee of the College of Physicians and Surgeons before it was merged with

WILLIAM H. DRAPER, M.D.

Columbia, and in 1889 he was elected to serve the university until his death.

Dr. Draper's connection with the New York Hospital was a long and interesting one. He was appointed attending physician in 1862 and continued to act as such until 1889, when owing to illness he resigned and was appointed consulting physician. But he got lonesome after all his years of active service as attending physician, and resigned as consulting physician in 1893 to be appointed attending physician again. It was a very rare thing for a physician to do, to resume active work. Dr. Draper served as attending physician until 1900, when he resigned, and he was then again appointed consulting physician. This makes his service of the institution one of thirty-nine

years, five years longer than that of Dr. James McLane, Dean of the College of Physicians and Surgeons, and nine years less than that of Dr. Markoe.

In addition to the New York Hospital Dr. Draper was connected with St. Luke's, the Presbyterian, Trinity, Roosevelt Hospitals, the New York House of Mercy and the Northwestern Dispensary. He was appointed attending physician at the Roosevelt Hospital upon its organization in 1871 and resigned in 1897, whereupon he became consulting physician there. He was President of the Medical Board of Roosevelt in 1883.

Dr. Draper made a trip of inspection to the Peninsula in connection with the Sanitary Commission during the Civil War. He was at one time President of the Alumni Association of the College of Physicians and Surgeons. In 1886 he was President of the College of Physicians and Surgeons and President of the Academy of Medicine. He belonged to the Academy of Medicine, the County Medical Society, the Pathological Society and the Physicians' Mutual Aid Association. In his early life he was a special student under Dr. Willard Parker, serving, under the custom of the time, as Dr. Parker's assistant, being succeeded in that post by Dr. E. W. Lambert, who with the late Dr. Henry B. Sands was an associate of Dr. Draper's for many years, these three well-known New York physicians having been born within a few months of one another. Dr. Draper before going to Europe in the fifties was an interne at Bellevue Hospital.

The ablest summary of Dr. Draper's personal attainment is that given by Dr. William Osler in an editorial notice in the New York *Sun*, which we here give entire.

"Tender memories and keen regrets will be awakened in the minds of many physicians all over the country at the news of the death of Dr. William Henry Draper. It has been given to a few men to adorn the profession with greater graces of the head and of the heart. He belonged to that rare group of men whose daily routine is a benediction, and whose very presence is a benison.

"As a teacher Dr. Draper had a keen sense of proportion in the subjects under discussion, and the merit of lucidity. One felt, too, in listening, a trustfulness in his honesty, and a faith in his convictions. A voice of uncommon sweetness, a singularly attractive face, and a winning manner lent special charms to him as a speaker.

"While not a voluminous writer he made many and valuable contributions to the literature of his profession. With the late Dr. Seguin he introduced the study of thermometry in this country. On the subject of gout and disorders of metabolism in general, Dr. Draper wrote as one having authority.

"But it was as a practitioner and consultant that Dr. Draper will be long remembered. He had in full measure 'that wisdom which results from combining knowledge with the instinct and skill for its useful application'—words which he himself used in describing the modern practitioner of medicine. Of his generation it would be difficult to name a man more beloved by his patients or more esteemed by his pupils and his colleagues. I express the feelings of his professional brethren in the Association of American Physicians, of which he was a founder and one of the early Presidents, when I say that in our discussions we listened to no one with greater attention, and the younger men among us looked on him as in all respects the ideal physician. Rare grace of presence, with a quiet dignity and reserve, made him a marked man in our gatherings, and his genial and unfailing courtesy and sweetnes of manner gave him an unrivalled popularity 'The too, too slow relief of lingering fate' he bore with a becoming patience and equanimity, and while restful death came to him as a longed-for friend, to us the joy in his release is tempered with sorrow at the thought that we shall see his face no more."

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, April 22, 1901.

THE REFORM OF THE BRITISH MEDICAL ASSOCIATION—PRIVILEGES OF ITS MEMBERSHIP—ITS SCIENTIFIC WORK—ITS POLITICAL WORK—THE SLOW GRINDING OF ITS MILLS—CAUSES OF THE PRESENT DISCONTENT—THE COUNCIL AND THE MEMBERS—THE CENTER OF GRAVITY IN THE GOVERNMENT OF THE ASSOCIATION—A "NAPOLEONIC LEGEND" IN THE ASSOCIATION—THE FRAMING OF A NEW CONSTITUTION—A BATCH OF DECORATIONS FOR MEDICAL MEN.

AMONG the medical questions of the day here may perhaps be counted the reform of the British Medical Association. I say "perhaps," because although a good half of the medical profession in these islands belong to that body, very few take any particular interest in its affairs. For a subscription of a guinea (about four and a half dollars) members get a good medical journal, and the right to attend an annual meeting in which the Horatian precept as to blending the agreeable with the useful is fulfilled by a judicious mixture of scientific papers and picnics. With these privileges the bulk of the members of the Association are content. They receive their *Journal*, which they do not read, but the sight of which seems to give them a sense of satisfaction akin to that felt by a Eunuch in the possession of a harem; and they go year after year to Edinburgh, or Birmingham, or Chelten-

ham, to keep their brethren informed of their continued existence and to proclaim *urbi et orbi* their most recent inspiration as to the treatment of a colic or the curve of a catheter. Beyond such simple joys they look for nothing from the Association.

Owing mainly to the popularity of its *Journal* the Association has for a long time been steadily growing in prosperity, and it has a surplus revenue which for some years has averaged £4,000 ($20,000). It has bought itself a considerable amount of real estate, including a large house in the most central part of London, Charing Cross, where even last century there was to be seen, according to Dr. Johnson, "the full tide of human existence." In that house there are not only offices for the transaction of the business of the Association, accommodation for the editorial staff and composing-rooms, but a considerable library which only needs a little more enlightened liberality in its management to become one of the most important in the Kingdom. In this library besides opportunities (in Matthew Arnold's phrase) of learning the best that is said and done in the medical world, members can write letters, transact business and interview friends as in a club. These varied advantages are greatly appreciated as is shown by the large and ever-increasing number of its members who avail themselves thereof.

The British Medical Association, as is set forth in its articles of association, was established for "the promotion of medical and the allied sciences, and the maintenance of the honour and the interests of the medical profession." The former of these purposes is fulfilled by the foundation of scholarships for the encouragement of original research and by grants in aid of special investigations; subventions are also given from time to time to the Jenner Society (which is the defender of the true faith against those whom Jenner himself called the "antivacks"), the Liverpool School of Tropical Diseases, the Congress of Tuberculosis, etc. The amount spent for such objects in 1900 amounted to more than £1,000 ($5,000). From time to time, too, committees of investigation on such matters as cancer, inebriety, the decay of children's teeth, the eyesight of railway servants, anesthetics, etc., are appointed, all of which involve more or less expense. Whether the Association gets adequate value for its money may be doubted. The Anesthetic Committee, for instance, sat for ten years, and after this prolonged incubation produced a report which though imposing in bulk and "horribly stuffed," as Iago says, with statistics, is scientifically and practically an addled egg. An elaborate "collective investigation" on cancer was equally barren of any solid result. Some years ago there was a Committee on Hypnotism which presented a report that was quietly suppressed by the Council as being likely to make the heathen blaspheme. An inquiry on the alcoholic question not only failed to throw much light on the matter, but stated its results with such curious infelicity of expression that the British Medical Association has ever since been quoted as teaching that abstainers are inferior to moderate drinkers in regard to expectation of life. Nor has the work done by the research scholars been as a whole of any great importance. The fact remains, however, that the Association spend a considerable sum of money each year, according to its lights, in the furtherance of scientific inquiry, and it is its misfortune, rather than its fault, that it has not yet found a mute inglorious Pasteur or Koch to whose genius "by poverty deprest" it could give the means of soaring.

With regard to its work in what may be called the political sphere, it must in fairness be admitted that the British Medical Association has on the whole done good service not only for the profession but for the public. Early in its career when it was comparatively a small and unimportant body it was instrumental in getting the first Vaccination Act passed in this country. It played the part of midwife in the process of legislative labor which ended in the birth of the Medical Act of 1859, and it may be called the actual begetter of the Act of 1886, the medical dispensation under which we now live and have our professional being. To the Association is mainly due such improvement as has in recent years been effected in the status and pay of the medical officers of the army, and it has taken an active part in the promotion of many useful reforms in our Poor Law, sanitary and lunacy administration. And its unostentatious work in adjudicating on ethical points and in supporting doctors in the public service against the insolence of office should not be forgotten.

But it may justly be said of the British Medical Association that its mills grind very slowly. Its committees as a rule meet but once a quarter, and a vast amount of time is lost in picking up the threads left loose at previous sittings. This fact lends some color to the charges of inefficiency and want of vigor brought against it by its critics. These consist of a few ardent spirits who think that things in general need reforming and they are the persons to reform them, with the usual following of busybodies in search of advertisement, malcontents whom in the words of Carlyle "no man's endeavour would satisfy," and cranks who are on principle "agin the government." The Association is governed by a Council the members of which are for the most part elected by the Branches between sixty and seventy in number; there is, however, a small number of former office bearers who have the title of Vice-President and as such have seats in the Council. These form but an insignificant proportion of the Council, and not many of them take the trouble to attend meetings so that their influence on the government of the Association is infinitesimal. Personally the Vice-Presidents are highly estimable old gentlemen, most of whom have grown grey and intellectually somewhat fossilized in general practice. Such influence as they have is derived from their character

as *viri pietate graves*. But there appears to be a pretty widespread feeling that they should no longer even in an ornamental sense have seats at the Council board. It is plain enough that this feeling has no nobler source than the jealousy which led the Athenian of old to vote for the ostracism of Aristides because he was tired of hearing him called "the Just"; but unworthy as it is, the feeling must be reckoned one of the forces making for revolution within the Association. Something of the same feeling is extended to the Council as a body, which is charged with many high crimes and misdemeanors, all of which may be summed up in the allegation that it is too conservative and is obstinately opposed to all reform.

There has, of course, always been a party who denounced the Council and all its ways, on the general political principle that it is the business of an opposition to oppose. But this party was till recently too insignificant, qualitatively as well as quantitatively, to have any weight either with the bulk of members of the Association or with the profession at large. They used to go to the annual meetings and pass resolutions which the Council treated as the protagonists of Greek tragedy receive the admonitions of the Chorus. It had never been clearly determined where the center of authority in the Association really was, and the Council having the reins in their hands acted on Bismarck's principle *Beati possidentes*. As the tide of agitation seemed to be rising, they deemed it prudent last year to have the power they had usurped confirmed by legal opinion. They accordingly sought counsel of an oracle of the law who to their surprise and discomfiture reversed the action of Balaam and cursed what he was called upon to bless. With the fatuity which, according to the ancient maxim, is sent by the higher powers upon those whom they mean to destroy, the Council concealed the opinion that they had got from their lawyer long enough to give rise to the impression that they wished to suppress it altogether. Driven to bay at last, they appealed to the *plebs* of the Association in special meeting assembled only to be ignominiously routed.

From first to last the Council, or rather its inner ring of active rulers, have shown a spirit of shuffling and evasion which has naturally produced the worst possible effect by giving rise to the notion that there were all sorts of misdoings to hide. As a matter of fact the affairs of the Association have been conducted with perfect integrity, and the only faults that can fairly be laid to the charge of those responsible for its management have been want of judgment, activity and intelligent initiative. But, though there have been no crimes, there have been many blunders, and they have too often been blunders of the kind that Napoleon said were worse than crimes.

The readiness to believe evil of the powers that be in the Association is a legacy inherited by the present from a past generation. As Shakespeare says, "The evil that men do lives after them"; though in this case it cannot be said that the good has been interred with their bones, for, oddly enough, there is now a marked tendency (in ill-informed quarters, it is true) to give the *ex hypothesi* illustrious dead vastly more credit than is due to them. As there is a revival of the Napoleonic legend in France, there are signs of a revival of a corresponding legend in connection with the British Medical Association. The coincidence is made all the more remarkable by the fact that the hero of the legend when alive rejoiced greatly in the description of "the Napoleon of medical journalism" which in an ill-inspired oratorical flight was bestowed upon him by an American post-prandial speaker.

The legal decision that the Association, being registered under the Companies Act is in the same relation to its members that a commercial enterprise is towards its shareholders, placed its destinies in the hands of the annual meeting. As this is simply a fortuitous concourse of atoms, which is usually attended only by the officers of the Association and a handful of cranks, it was obvious that at any time by judicious lobbying a snatch vote might be passed by which the whole concern would be wound up or the Association committed to homeopathy, antivaccination or any other folly. Something had to be done, and Mr. Victor Horsley came forward as a savior of society and proposed the appointment of a Committee to frame a new constitution for the Association which was showing signs of tumbling *mole suâ*. This committee sat through the winter and drew up an unwieldy scheme of reform which is now being discussed by the Branches. In a future letter I will give an outline of the scheme, which as far as can be gathered from the voting up to the present, will be accepted. It should be said, however, that only an inconsiderable fraction of the Association take any interest whatever in the reform.

TUBERCULOSIS—SPINAL ANESTHESIA—PUERPERAL INFECTIONS—PRIMARY RESECTION OF THE DIAPHYSIS OF THE HUMERUS.

Robin, at the Académie de Médecine, March 19, 1901, discussed the subject of the conditions and diagnosis of tuberculosis among mankind, basing his observations upon the results of data secured by Binet and himself, through several years past, of 392 patients. The facts enunciated tend to combat many of the false notions about tuberculosis held by the laity and physician alike. For example, it is held that the usual lung activity of the tuberculous is far below that of the normal chest, whereas the opposite is the rule. Consequently the practitioner is desperate in his efforts to increase the oxidizing functions. In 162 cases carefully determined in

only 8 per cent were these conditions found to be correctly diagnosed in the popular notion. The variation from the falsely-assumed rule may be summarized as follows: Pulmonary ventilation increases about 110 per cent. in the female and 80.5 per cent. in the male; carbonic acid exhaled by the kilogram of weight and by the minute increases by 86 per cent. and 64 per cent. respectively in the woman and man; total oxygen consumed to the kilogram-minute increases in the female 100.5 per cent., in the male 70 per cent.; total oxygen absorbed by the tissues rises by 162.8 per cent. and 94.8 per cent. each in the female and the male sex. This superactivity of the pulmonary changes is present also in the acute stages and forms of the disease, and is always openly manifested in the chronic cases. It accompanies alike the periods of invasion, of advance and even of fatal termination up to almost the last moments. It is capable of oscillations which tend to show those periods which mark the advance, quiescence and recurrence of the process. Sufferers from tuberculous spondylitis, osteitis, osteomyelitis, orchitis, pleuritis, and adenitis, all conform to these rules of greater activity of the body-changes. They are, however, absent in the presence of peritonitis, meningitis and lupus of tuberculous character. There are several diseases and conditions which are accompanied by an exaggeration of the respiratory function, but in such the nature of such variations differs from that in phthisis. Therefore, if one hesitate about diagnosticating tuberculosis, a study of the respiratory changes will be likely to establish the question and since they occur with the invasion it will be possible to do so very early in the disease. The exaggeration of the respiratory function does not appear to be an act of defence by the system, nor a sign of the attack of the baccilli, since it exists in three-fourths of the offspring of tuberculous parents before any disease has appeared. In conditions regarded as antagonistic of tuberculosis, for example, arthritism, the respiratory functions are less than normal. These respiratory exaggerations may, therefore, be regarded as one of the ground or soil elements for tuberculosis and one of the others is the disintegration of the tissues, so that with Hippocrates we may regard tuberculosis as a consumption. It is this hyperoxidation and demineralization of the tissues which constitutes the soil for the invasion of the disease. The prophylaxis and cure of tuberculosis does not rest entirely with the means, public and private, commonly adopted against it. It consists in selecting persons probably susceptible to it and putting them under such hygienic and therapeutic influences as will tend to counteract the invasion of the bacilli.

Reclus in reading a paper, collaborated with Tuffier, on the subject of general anesthetization with cocaine injected into the spinal canal, dwelt briefly on the details of the technic and its dangers and difficulties. In the first place it is not easy to enter the subarachnoidean space always. Then, when the injection has been made the actual anesthetic effects may be very much delayed, entirely absent, very imperfect or very ephemeral. In addition to these which might be dismissed as insignificant are those which are certainly within the category of serious sequelæ. Among such are severe headache persisting many days and causing insomnia; paresis of either or both lower extremities, also apt to continue a long time; failure of rectal and vesical control, both during and after the operation; nausea and vomiting which have been known to exist for many days; muscular tremors or general trembling have been seen. All these one author claims can be disregarded when one considers the dangers of ether and of chloroform narcosis, but such is not the truth. Out of a total of only 2,000 spinal cocainizations six, possibly eight, deaths are to be attributed to the cocaine alone, although small doses were employed. Among many thousand records chloroform shows 1 death in 2,300; ether, 1 in 7,000; subcutaneous injections of cocaine, 1 in 7,000. Hence one must conclude that these three last named are the best anesthetics for all-round surgical use.

Laborde, at the meeting of March 26, 1901, continued the subject by stating that for several years he has made experimental cocaine injections into the arachnoidean space with special reference to its hazards and has concluded that these are so real that the method should be abandoned for ether and chloroform narcosis. The dangers encountered are due either to deleterious local effects of the injection upon the nerve substance, or to absorption of the drug and diffusion of it through the spinal fluid so that the bulb is reached. Then occur the profound circulatory and respiratory depressions, the nausea and the vomiting, the severe headaches and so on, according as one or another center is affected. Consequently the method should be proscribed as too dangerous.

Ricard, at the Société de Chirurgie, March 13, 1901, spoke of the indications for operative interference in cases of puerperal infection and said that the primary step consists in determining the character and the extent of the lesions. The cases come usually within two categories. There are such as have a local peritonitis or lesion. Treatment must therefore comprise a determination of the limits and locus of such lesions and an appropriate operative intervention according to the findings. There are also those cases which are in fact a general peritonitis. In these treatment must be concerned with deciding whether or not to interfere at all and if so the fitting time and procedures of it. The total statistics of the French accoucheurs comprise about 2,640 cases of puerperal infection. Of these 105 were fatal. Of the grand total 805 showed a temperature of 39° C. or above, which would make the mortality-rate among them 13 per cent. In general terms the rate of mortality among the French in this class of cases is about 10 per cent. and this without any intervention

except that which the usual methods comprise, that is no hysterectomy. After gathering all these statistics and carefully studying them, he has not been able to find one single indication among all the number which might be regarded as definite for hysterectomy. Upon the basis of this evidence he does not hesitate to declare against hysterectomy unless a very definite indication can be obtained from the circumstances of the case. In general terms the ordinary treatment of puerperal infection is adequate.

Picque, in behalf of Studer (Vernon) and Radouan (military surgeon), reported a case of gunshot wound of the humerus necessitating primary resection of the diaphysis for an united fracture. The result obtained by these two observers in this case was very excellent and satisfactory. He went on to relate a case of his own in which a crushing accident had been followed by pseudarthrosis between the two fragments of the broken humerus. Apparatus applied had proved most unsatisfactory and he had thought that a primary resection of the diaphysis would have been more advantageous. Nélaton said that in the matter of primary diaphyseal resections of the humerus it was impossible to formulate any fixed rule. In the first place it is necessary always to spare the skeleton as much as possible and to content one's self with the removal of splinters of bone and the smoothing and apposition of the larger pieces.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

Sixteenth Annual Meeting, Held at Washington, D. C., April 30 and May 1 and 2, 1901.

First Day—April 30th.

President's Address.—Dr. William H. Welch said that the day for formal addresses before such a body as the present one had gone by and on this, the sixteenth anniversary of the Association, he wished to allude only to a few points of present moment. He contrasted the present splendid opportunities in American medicine with those of fifteen years ago when this society had its birth, but, he added, the growth had not progressed along symmetrical lines. To-day, the opportunities for research and laboratory work in anatomy, and pathology and the more strictly technical branches of medicine were unexcelled in any country in the world and the strongest feature in the developmental history of the teaching of medicine in the United States was the superb opportunity offered in laboratory research, but that the scientific post-graduate work in clinical medicine had not been developed as it should be. In clinical medicine the few years in the hospital and others in dispensary work now afforded did not give that opportunity for careful clinical work which was the regular routine in the universities of Europe. The further development of the post-graduate work as hospital residents was a step that our teachers should encourage. In speaking of the overcrowded condition of the society, with practically no vacancies and a pressing waiting list, he called the attention of the members to the advisability of acting on Dr. Da Costa's suggestion of placing those members who were not in active membership on the honorary roll and thus permit the younger and more active members of the profession to enter their ranks. In a few admirably chosen words he spoke of those members who had died during the past year—Drs. J. T. Whittaker, J. M. Da Costa, S. C. Bussey and W. H. Draper.

Official Business.—The Reports of the Secretary and Treasurer were read and the names of ten applicants for membership were presented to be voted on. These were Drs. C. L. Greene of St. Paul, Wm. T. Howard, Jr., of Cleveland, George Blumer of Albany, Alfred S. Warthin of Ann Arbor, J. J. Kinyoun of U. S. Marine-Hospital Service; E. K. Dunham of New York, J. L. Morse of Boston, H. Jackson of Boston, A. R. Edwards of Chicago; for honorary membership, Dr. Charles F. Folsom of Boston.

Slow Pulse and Stokes-Adams' Disease.—This paper by Dr. Robert T. Edes of Boston was read by title.

Undescribed Cardiac Sound.—Dr. H. A. Hare of Philadelphia described a peculiar vibration occurring at the systolic interval, one inch to the right of the sternum, and one inch to the left of the nipple on the nipple level which did not correspond to any sound with which he was acquainted. It resembled, in part, a pericardial friction sound, but was dryer and was due to the contractions and vibrations of the chordæ tendinæ, especially when the heart muscle was not perfectly normal. In certain ways it closely resembled the sound "ching," short and quick and not too crisp. It was increased by mental excitement and fear, but not by muscular exercise.

Diagnostic Significance.—He had come to regard it as evidence of impaired myocardial action and had found it frequently following influenza, in the depressed physical condition. In the beginning of pulmonary tuberculosis it was a valuable diagnostic sign. It was not a subjective cardiac symptom.

In discussion Dr. Osler said he thought that possibly the sound was to be interpreted either as the first sound, with a peculiar crunching character or it was the delicate sound, slightly grating, which is frequently found at the apex resembling a pericardial friction sound.

Flint Murmur in Aortic Insufficiency.—In speaking of the frequency and the diagnosis, Dr. W. S. Thayer of Baltimore referred to the murmur first described by Flint in 1862; this was presytolic and limited to the cardiac apex.

The sound was loud and blubbering and had all the characters of a mitral, direct presystolic murmur. In view of the fact that Gibson, in his recent text-book, says that he had not encountered this condition, Dr. Thayer had made a complete analysis of the cases presenting Flint's murmur in the wards of Dr. Osler in the Johns Hopkins Hospital. Since May, 1889, 74 patients with aortic insufficiency came to autopsy. In 45 of these there was heard at some time a rumbling, echoing murmur in diastole, limited to the region of the apex, and differing from the diastolic murmur of aortic insufficiency, *i.e.*, a murmur similar to that of mitral stenosis. It was presystolic in time and ended abruptly in a first sound or a systolic murmur. In 12 of these 45 cases there was a mitral stenosis associated with the aortic lesion. The results of an examination of 58 cases of aortic insufficiency showed that 33 had the Flint murmur. In 17 out of the 33 cases in which a Flint murmur was observed, the mitral valve was normal. Dr. Thayer propounds the question whether it is possible to distinguish positively the cases of aortic insufficiency with Flint murmur from those complicated with mitral stenosis during life. The more characteristic physical signs of mitral stenosis are the pulse, the sharp systolic shock at the apex, the presystolic or mid-diastolic apex thrill and murmur, and the sharp valvular first sound in the apex region. An analysis of the physical signs in 22 cases of uncomplicated mitral stenosis shows that the thrill was present in 54½ per cent., a sharp, systolic shock and snapping first sound in 68 per cent. and a presystolic murmur in 81 per cent. of the cases. A comparison of the cases with mitral stenosis and aortic insufficiency combined shows no very great differences except with reference to the sharp shock of the first sound.

Combined Lesions.—The tables quoted by the author bring out certain clearly marked clinical differences between the cause of aortic insufficiency with Flint murmur and those complicated with true mitral stenosis. The character of the murmur differs only in that the Flint murmur is never as rasping and intense as are the more marked murmurs of true mitral stenosis; it is commonly echoing and of moderate intensity. A large proportion of cases of true mitral stenosis, however, show similar slight thrills. The presystolic thrill is less frequent and less intense. In but a very small number of cases of aortic insufficiency with Flint murmur does the apex beat have the tapping character so significant of true mitral stenosis.

History of Cases Important.—In the 33 patients with Flint murmur there was a clinical history of acute rheumatism or chorea in but 13. In more than half there was clinical evidence of general arteriosclerosis although arteriosclerotic changes offer no diagnostic features, being as common in one type as another, whether the Flint murmur is absent or present. Arteriosclerotic lesions are usually located at the aortic orifice; in endocarditis the greater prevalency of mitral involvement is important.

Diagnosis.—A positive diagnosis of functional mitral presystolic murmur is difficult to make as it may differ in no way from true mitral stenosis. In true mitral stenosis, however, even if complicated with aortic insufficiency, the tapping systolic shock and the snapping first sound are common. On the other hand, the Flint murmur is associated usually with the characteristic heaving impulse of aortic insufficiency and the dull ill-defined, prolonged first sound. In cases of Flint murmur the pulse is usually wholly characteristic of aortic insufficiency. The diagnosis of Flint murmur is fairly safe when a presystolic murmur in the region of the apex is present in aortic insufficiency occuring in individuals with well-marked arteriosclerosis, especially in the absence of history of any acute malady ordinarily associated with the development of an endocarditis.

Dr. Cabot of Boston, from the results obtained in the wards of the Massachusetts General Hospital, bears out Thayer's results. In 10 patients coming to autopsy, showing during life this murmur, there were normal mitral valves.

Cause and Clinical Features of Cardiac Hydrothorax.—Dr. Alfred Stengel of Philadelphia limited his paper to the discussion more particularly of right-sided hydrothorax. Most writers regard pleural dropsy of cardiac disease as bilateral or unilateral only when one pleura is bound down by adhesions. In the study of 100 patients with cardiac disease he had 17 with hydrothorax. Five of these were right-sided alone, 3 left-sided, in two of which the right pleura were adherent. Nine were bilateral at one stage or other of the process. Two began as right-sided hydrothorax and then became bilateral, the others started as bilateral lesions.

Etiology.—The reason for the marked preponderance of right-sided lesions does not appear to be an accidental one. Stengel discards all the inflammation theories and supports those based on anatomical causation. The condition may be due to obstruction to the lymph channels or what is more probable to pressure on the venous circulation, more particularly to some mechanical obstruction to the vena azygos major.

Clinical Forms of Heart Disease Showing Hydrothorax.—From autopsy findings the author had found this condition in 73 per cent. of the cases in which there was mitral disease and only 17 per cent. in which tricuspid disease was present. Hence the enlarged right heart due to mitral lesions might be regarded as an efficient cause of pressure on the azygos vein. The difference in anatomical configuration of

the right and left sides might be regarded as influencing this one-sided involvement.

In the discussion Dr. Osler said that the cause of the affection pointed clearly to a local affection because of (1) its chronicity, the affection lasting for years and recurring year after year; (2) because there is absence of edema in other parts of the body, and (3) because it is almost invariably right-handed.

Dr. J. C. Wilson of Philadelphia said that when the affection was bilateral it was frequently due to renal causes: he also said, in discussing the cardiac cases, that probably the anatomical fact that the heart, itself, occupied such a large part of the left pleural cavity was sufficient reason why the right pleural cavity was oftener affected.

Dr. E. G. Janeway of New York, in commenting on the difficulties in diagnosis, reported a case of typical right hydrothorax without valvular lesions, which was diagnosed by one eminent consultant as tuberculous in origin; by another as not a case of heart disease; by a neurologist as a case of Bright's disease, as renal symptoms had appeared in the meantime. An autopsy developed the fact that the patient had had a myocarditis fibrosa and died with a thrombus in the left ventricle.

Dr. A. Jacobi spoke of the frequently unrecognized occurrence of myocarditis diagnosed as mitral disease. The possibility of local myocardial degeneration should be borne in mind. This alone might induce a local hydrothorax.

Chronic Myocarditis and Fatty Degeneration of the Heart.—Dr. Beverley Robinson of New York City said that clinically these two conditions of cardiac degeneration are frequently most difficult to differentiate. The symptoms denoting cardiac weakness are slowness of the heart sounds at times, alternating with extreme rapidity, with sensations of fluttering and cardiac distress. Sometimes there is a systolic murmur. Attacks of dizziness or faintness may come on rapidly and repeat themelves with little or no sufficient cause. The pulse is often faint and there is an occasional lapse of one or two beats. This type he believes is due to a beginning fatty degeneration and are best treated by iron and arsenic in order to restore the anemic blood condition which is an invariable precursor. Intestinal antiseptics are also of service. Strophanthus and strychnine are demanded at the time and the systematic use of oxygen is beneficial.

Causes of Cardiac Degeneration.—These were dwelt on at some length. Obesity, senility, muscular exertion, gout, and syphilis were all discussed as factors in the causation of these destructive heart lesions. In senile hearts, among those who have led moderately careful lives the changes are apt to be a fibrous rather than of the fatty type, if the heart begins to show decided weakness, irregularity and intermittency. With these conditions there may be moderate enlargement—usually hypertrophic dilatation. The arteries are apt to be thickened and tortuous. The urine, while not showing any sugar or albumin, is ordinarily of low specific gravity and the whole quantity is diminished. With fatigue or dietary indiscretions, prolonged exposure to heat or cold the heart is apt to make the patients suffer. They sleep poorly, bronchitis may develop, and they frequently have faint and dizzy spells. These patients are those suffering from myocarditic changes.

Hemorrhage from Pleural Abscess.—Dr. A. Jacobi of New York reported a case of empyema occurring in a child of three years of age. Rib resection was practised and after 500 c.c. of pus had been evacuated a large hemorrhage occurred which was checked by packing with gauze. The hemorrhage was very profuse and came from a number of disseminated tufts arising from the pulmonary pleura. These tufts varied in size from mere pinheads to ½ cm. in diameter. The treatment by compression was satisfactory and the child ultimately recovered. He believed the case to be unique, as it seemed that the most important etiological factor, tuberculosis could be ruled out.

Cyst of the Omentum.—Dr. Jacobi also presented a specimen of simple cyst of the omentum occurring in a child two years of age. The affection was at first diagnosed as tuberculosis of the peritoneum and the abdomen was repeatedly tapped, with success, for a year. The tumor recurred and again subsided after tapping. On the appearance of inflamed axillary lymph-nodes, a laparotomy was performed and an enormous cyst was removed by Dr. Weir. This proved to be a simple uncomplicated cyst of the omentum, attached by two pedicles with numerous channeled cystic cavities. The child made a complete recovery.

In discussing Dr. Jacobi's first case Dr. J. P. Henry of Philadelphia remarked that, inasmuch as tuberculous pleurisy was very common and hemorrhage of the pleura was rare, tuberculosis could not be rightly considered as the main cause of hemorrhage of the pleura. In his experience scurvy was the most important etiological factor.

Dr. G. L. Peabody of New York said that there were undoubtedly many cases of hemorrhagic pleuritis which were never diagnosed because they recovered. Many of them might be tuberculous and yet not be diagnosed as such. Many cases diagnosed as pleurisy with effusion showed hemorrhage on tapping.

Dr. Osler commented on the fact that it was in the early stages, when the fresh tubercles were being formed, that hemorrhage was apt to occur.

Pneumonia with Remarkable Exudate.—Dr. Charles Cary of Buffalo reported a most remarkable case of extensive pseudomembranous exudate occurring in a case of acute lobar pneumonia in a boy eleven years of age. The disease began as a simple tonsillitis, with sore and reddened throat, no membrane and negative bacterial findings. The boy subsequently developed a temperature of 103.5° F., and the lungs finally became consolidated. The picture was that of an acute

double lobar pneumonia. A thick, tenacious, fibrinous exudate formed in the mouth and fauces and on the nasal mucous membrane. This the boy would pick off and beneath the exudate there would be left a raw, granulating surface. A similar membranous exudate developed over the glans penis, but this did not extend into the urethra. There also developed a marked tympanites and a similar membranous exudate was found on the mucous membrane of the rectum. A fibrinous pleurisy was also diagnosed.

Pneumonic Character of Exudate.—Microscopical examination of the exudate showed it to be composed of fibrin and pus and there were numerous diplococci of pneumonia. Streptococci were also present, but the bacillus of diphtheria and Neisser's gonococcus were absent. Animal inoculations demonstrated the pneumococcic character of the infecting agent. The patient ultimately recovered after a three months' illness.

Pernicious Anemia.—Dr. F. P. Henry of Philadelphia reported on a number of cases of pernicious anemia which he discussed at the last meeting of the Association in 1900. He said that the tendency to regard megaloblasts as pathognomonic was unnecessary. The diagnosis was better founded on the general signs and symptoms in addition to the blood findings. Nucleated cells were not indicative of pernicious anemia solely, since they were found in other conditions, notably in *bothriocephalus latus* infection. He felt that a clinical diagnosis was to be preferred to a laboratory investigation; thus bothriocephalous anemia was not separable by microscopical means from cryptogenic anemia.

Progress of Pernicious Anemia.—Dr. Frank Billings of Chicago discussed similar cases reported by him in 1900. He showed by an admirable series of charts the general progress of a number of cases. Of twenty patients reported ten had died, of the remainder four were under observation. He brought out the fact that with a decided decline in the patient's condition, Van Noorden's crises, there appeared a large number of nucleated red cells, although a few cases did not follow this general law. The continued observation of the cases had not developed any new facts save that the periods of improvement in some were longer than is usually taught in the text-books.

Volume Index.—In view of the uncertainty of blood counts, Dr. Billings in collaboration with Dr. J. A. Capps, of Chicago, had elaborated a new unit, entitled the volume index. This represents a fraction whose numerator is the percentage of red-cell count as determined by the hematocrit and whose denominator is represented by the percentage of red-cell count as determined by the Thoma-Zeiss hematocytometer. This volume index bears a certain ratio to the color index which is the fraction whose numerator is represented by the percentage of hemoglobin and denominator by the percentage of red blood-cells as determined by the hematocytometer.

Spinal Cord Changes.—Dr. Billings reported on one patient that developed the typical spinal cord lesions of pernicious anemia reported by Noune, Dana, and other observers. The clinical picture and pathological findings were typical. The spinal cord degenerations as reported on by Dr. L. F. Barker, of Chicago, were mainly confined in the lumbar cord to the efferent tracts—the column of Goll and Burdach, the direct cerebellar tract and Gower's tract. In the cervical cord the lesions were more diffuse, being almost myelitic in character.

Dr. James J. Putnam in discussion asked if the changes in the cord were pathognomonic of pernicious anemia. He was inclined to hold that in other conditions, more particularly of malnutrition, similar cord changes might be found.

Dr. Osler drew attention to a type of spinal cord lesions, preceding the development of the pernicious anemia, as outlined by Risien, Russell, and Battey of England.

Dr. Shattuck of Boston spoke of pernicious anemia following sudden mental shock and reported a case occurring in a healthy woman following the sudden death of a son.

Acute Splenic Miliary Tuberculosis.—Dr. D. D. Stewart of Philadelphia reported an unusual case of acute miliary tuberculosis originating in the spleen. The patient was a trained nurse, who after protracted work with a typhoid case contracted an influenza and before fully recovering commenced to nurse a tuberculous patient. Bad general hygienic surroundings, poor food and reduced vital tone were the probable factors predisposing to the infection. She was sick sixty-eight days and died of acute general miliary tuberculosis with extensive involvement of the spleen. The spleen was first attacked and showed the oldest and most extensive lesions.

Relapsing Fever of Hodgkin's Disease.—Dr. J. H. Musser, of Philadelphia, considered in detail the peculiar relapsing fever of pseudoleucemia, which he regarded as possibly tuberculous in its character, although its remittent type was peculiar and not absolutely typical of that condition. He reported several cases and spoke of some of the prodomata of the fever, as mental irritability, pain in the glands of the groin, anorexia and most obstinate insomnia. The blood was negative and the treatment unsatisfactory.

Dr. W. H. Welch spoke of the gradually growing conviction in pathological circles that a large number, if not most of the cases of Hodgkin's disease were tuberculous in their character.

Blood in Lead-Poisoning.—Dr. Alfred Stengel, described for Drs. C. Y. White and William Pepper of Philadelphia, a type of degeneration of the red cells of the blood which was present in lead-poisoning and which when found offered a diagnostic aid in the study of this affection. It consisted of a granular degeneration of certain elements in the erythrocyte which became manifest by its reaction to certain basic anilin dyes, notably thionin. The granules are small, evenly distributed or clumped, varying from very minute puncta to granules the size of

eosinophile granules, round or club-shaped. They may be found in the normal or irregularly shaped red cell. They are not found in the fresh blood, but require starving technic to make them manifest. Stengel does not regard them as mitotic remnants of the nucleus, but considers them as true degenerations. His experiments included a series of patients with well-marked lead-poisoning, lead workers (clinically sound), cases exposed to high temperatures, and animal poisoned experimentally.

Diagnostic Features.—The granules are always present in well-marked cases of lead-poisoning; the more severe the grade, the coarser the granules. In cases of lead workers the granules were always present although clinically the patients were well. As the patients recover the granules disappear.

Toxic Origin of Neurasthenia and Melancholia.—Dr. M. Allen Starr of New York said that among the many types of neurasthenia there were at least four with fairly well-marked characters: There were those due to anxiety and mental distress; cases due to overexertion and stress; others due to beginning degeneration of the neuron and destined to go on to organic breakdown, and a fourth due to toxic causes. He limited his discussion to this last class. Here there seemed a definite cycle of symptoms; there was headache, fulness in the head, irritable temper, lack of ability to concentrate the attention, irregular flushings; dyspeptic symptoms; regurgitation, eructation, constipation, foul and feculant stools were common. There was a definite mental cycle. From noon until 9 P.M. the patient feels better, from that time the patient gets worse until 4 A.M.; when he awakes he is extremely depressed and remains so the entire morning. At noon greater cheer comes and the cycle repeats itself.

Etiology.—In as much as this definite cycle is manifest it must be dependent on a habit cycle of the patient. This, Starr thinks, is associated with gastro-intestinal absorption and hence the causative agent is of a toxic nature which he believes is formed in the stomach and intestines.

Treatment.—Regimen is paramount. Increased water intake and a diet peculiarly adapted to the individual patient. Drug treatment should be digestant and eliminant. Small doses, $^1/_{10}$ gr., calomel frequently repeated and combined with ¼ gr. doses of podophyllum, Carlsbad salts and sodium salicylate at morning meal. Intestinal antisepsis with sulphocarbolate of soda, gr. v, potassium permanganate, gr. i; or, salol, gr. v, castor oil, ℥ v; or sulphocarbolate of soda, gr. v, sodium benzoate, gr. v; beta-naphthol, gr. v. These remedies should be put up in capsules which pass into the intestine before setting free their contents. This medication will break up the periodicity; baths, exercise and rest will complete the cure.

Addison's Disease.—Dr. W. W. Johnston of Washington presented a man with Addison's disease, shown last year, who on suprarenal capsule had improved and was now able to do full work.

Neurasthenia and Its Recognition.—Dr. W. W. Johnston used the case of Charles Darwin as an illustration showing how the lack of recognition of the main causative factors in neurasthenia is responsible for many breakdowns and lost opportunities. The diversity of symptoms of the neurasthenic makes him a prey to the narrow-minded specialist, as in this condition there is such a "positive exuberance of symptoms." The treatment of gastric disorders offers but a very limited outlook in the treatment of the condition. Rest is of more value than medication, but of still more value is the education of the rank and file of physicians to the position of being able to recognize the condition.

Need for Sanatoria.—The author holds that there is a distinct need for special sanatoria for the treatment of this condition. Mixed cases should not be allowed and the attendants all should have had a special training. Educational blunders often condemn children to lives of invalidism and the offspring of neurasthenic parents should be carefully and soberly educated.

In discussion Dr. James J. Putnam said that his observations did not bear out the belief in a definite cycle in neurasthenics; cause and effects were extremely variable and difficult of accurate measurement. Well conducted sanatoria were much in demand.

Dr. C. A. Herter of New York referred to intestinal putrefactive products as bearing on the question of a toxic type of neurasthenia. The amount of excretion of ethereal sulphates was an indication of the grade of mental depression. In melancholia they were often much increased. Experiments on indol were referred to, this substance producing such toxic effects as increased nervous irritability and depression. There is a definite relationship which may be posited although perhaps the exact toxic product is not known.

Diabetes, Diabetic Coma and Acid Intoxication.—Dr. C. A. Herter read a highly suggestive and important paper on the relation of acid intoxication to the development of diabetic coma. In order to measure the amounts of organic acid, mainly di-acetic and B oxybutyric acids, he had followed two main methods, one known as the method of balancing acids and bases, the other by estimating the nitrogen of ammonia. In health, by the former method, it is found that, speaking generally, the acids and bases neutralize each other while in diabetes, especially approaching a period of coma, there is a marked increase in the total bases, measured as sodium, which indicates a much larger amount of organic acids with which the basic compounds combine, in order to neutralize the same. The method of determining by the N in NH_3 shows that in diabetic coma the amount of nitrogen is enormously increased.

Prophylaxis of Coma.—Both methods, therefore, afford valuable information bearing on

the developmental history of diabetic coma and offer valuable forewarning of the appearance of this complication. Inasmuch as the amount of sugar in the urine does not show any definite ratio to the amount of organic acids, it is obvious that the ordinary sugar tests afford little evidence on this point. Dr. Herter gave brief summaries of three groups of cases showing the relationship of the excretion of the organic acids to coma. Most cases showing increased amounts of organic acids, reckoned as B oxy-butyric acid, do badly; the reverse is not always true however. In his conclusions he said that the method of balancing acids and bases, as a chemical procedure, offered the best means of determining the exact quantitative relations of excretion of the organic acids; the determination of nitrogen, as ammonia, is useful as a clinical method especially from a prophylactic point of view; an increase of organic acids precedes and is coincident with diabetic coma; crotonic acid is usually present in the urine in diabetic coma; an increase of oxy-butyric acid may be present for a long time, days, weeks or months, before the development of coma, yet if the amount of organic acids in the urine is persistently over 25 grams daily, coma is certain to develop; cases with as much as 30 grams daily of oxy-butyric acid have been known to go about in comparative comfort; the ratio of glucose and acid intoxication is not constant and hence sugar determinations have little prognostic significance; a diminution in the amount of ingested carbo-hydrates usually diminishes the amount of excretion of organic acids.

Metabolism in Diabetic Coma.—Dr. E. P. Joslin of Boston corroborated in a striking manner the results of Dr. Herter in the recital of a case under the observation of Dr. Pfatt and himself. A rigorous alkaline treatment failed to save the patient when in coma.

In discussion Dr. Vaughan said that an excess of nitrogenous food often did harm, especially as these organic acids probably did not come from carbohydrate food.

Dr. Pfaff of Boston said that in the diet of diabetics it is wise to exclude fats very rigorously as most of the acetone is developed from such bodies. The irritation of the kidneys is often due to even very slight amounts of carbohydrates ingested. Acid intoxication is a step nearer the ultimate solving of the problem of diabetes, but underlying all were the deeper mysteries of perverted metabolism.

Dr. Herter said that he did not regard the failure of the alkaline treatment militated against the theory of acid intoxication. The trouble lay in the continued formation of new organic acids; moreover, the frequent success of the intravenous infusion of alkaline salts served to support the doctrine. He said that cutting off nitrogenous diet would be unwise, since, granting that some of the acids might come from proteids, the major portion of the neutralizing ammonia also comes from the proteids.

Classification of Poisons and Intoxicants.—Dr. J. G. Adami of Montreal gave a short dissertation on this subject, claiming that clearer ideas of terminology were of value. He offered a slight modification of Von Jakoch's system of classification.

Demonstrations of interesting specimens were given in the evening by Drs. C. C. Bond of Richmond, Ind.; William F. Councilman of Boston, H. C. Ernst of Boston, S. Flexner and R. M. Pearce of Philadelphia, W. H. Welch, E. L. Opie, W. G. MacCallum and Buckley of Baltimore.

Election of Officers.—J. C. Wilson of Philadelphia was elected President; James Stewart of Montreal, Vice-President; S. Solis-Cohen of Philadelphia, Recorder; Henry Hunn of Albany, Secretary; J. P. Crozer Griffith of Philadelphia, Treasurer; Frank Billings of Chicago, F. P. Kinnicutt of New York, Councillors; Wm. Osler of Baltimore, Member of the Executive Council of the Congress and F. H. Williams of Boston his Alternate.

(To be Continued.)

BOOK REVIEWS.

Lecons de Physiologie Experimentale. By Drs. R. Dubois and E. Couvreur. Georges Carré et C. Nand, Paris.

These lessons constitute an outline of the work in physiology given to the students of the University of Lyon and are put forth expressly with the purpose of saving the student's time and to relieve him from the task of taking and copying notes.

The work is more than a mere record, however, it is a carefully-prepared and well-illustrated guide to the study and practice of experimental physiology. It is particularly opportune and to be recommended warmly at this time when the methods of observation and experiment are taking the place of the dry-as-dust didactic lecture in some of the more advanced medical colleges of this country.

A Practical Treatise on Materia Medica and Therapeutics. By John V. Shoemaker, M.D., LL.D., Professor of Materia Medica, Pharmacology, Therapeutics and Clinical Medicine, Medico-Chirurgical College of Philadelphia. Fifth Edition. F. A. Davis, Philadelphia, New York, and Chicago.

Decidedly Dr. Shoemaker's book is very useful. From many points of view it is excellent, from others the reverse. Among its desirable features may be classed its thorough appreciation of the pharmaceutical side of the dispensing of medicines and its richness of practical hints in the use of drugs. Its prescriptions are numerous and well selected and from

a knowledge of a student's needs, we know that they are extremely useful.

The method of grouping drugs is alphabetical. For the student this appears to us to be detrimental to the value of a work of this kind. It, moreover, compels a repetition that is neither desirable nor necessary.

An Introduction to Physiology. By William P. Townsend Porter, M.D., Associate Professor of Physiology in the Harvard Medical School. The University Press, Cambridge, Mass.

The flood-tide of laboratory manuals has been in evidence in many branches of natural science, but thus far the student of physiology has been more consigned to monumental tasks of memorizing voluminous tomes termed physiologies.

We trust that the example set by Dr. Porter in this simple and accurate volume will be followed by other teachers and that laboratory methods of teaching physiology will be as universal as they are in the cognate branches of anatomy, pathology, and chemistry. The book is a laboratory guide and discusses the methods and why and wherefore of animal experimentation.

A Manual of Obstetrics. By A. F. A. King, M.D., Professor of Obstetrics and Diseases of Women in the Medical Department of the Columbian University, Washington, D. C. Lea Brothers & Co., Philadelphia and New York.

The art of midwifery differs somewhat from most other branches of medicine in that, from the very nature of things, very radical innovations in practice or theory are hardly to be expected in the course of a few years and though a guerrilla warfare is constantly being waged in the outlying borderlands that are concerned with such minor considerations as the value of antepartum douching, chloroform *vs.* ether, the dangers of the antepartum full bath, methods of treating the cord, etc., there is a gratifying unanimity of opinion on all important points and in the main the process of child-bearing is allowed to go on much in the same way that it has ever since the last great change was made after the discovery of the principle of antisepsis. Therefore the appearance of the present edition of this well-known handbook so closely on the heels of its predecessor must be taken, not as evidence of the rapid progress of the science it deals with, but as an indication of the popularity it has attained and of its usefulness to a large circle of readers. That the volume contains much less letterpress than do the more pretentious treatises is to be ascribed to conciseness of expression rather than to any omission of matter, for even a careful search reveals but few topics that are not well covered in the limited space devoted to them. It must be admitted, however, that the dismissal of the subject of artificial infant feeding is rather summary and that even a text-book on obstetrics intended primarily for students might profitably vouchsafe its readers more information on this head than is to be found in the single paragraph devoted to it. As a whole, the book is undoubtedly the most valuable shorter exposition of the subject that we have and it cannot be praised too highly for the use of students or even as a convenient reference work on practical points for practitioners.

A Text-Book of Histology, Including Microscopic Technique. By A. A. Böhm, M.D., and M. von Davidoff, M.D., of the Anatomical Institute, Munich. Edited by G. Carl Huber, M.D., Junior Professor of Anatomy and Director of the Histological Laboratory, University of Michigan. W. B. Saunders & Co., Philadelphia.

This book is a translation of one of the best known German text-books on the subject of histology. For variety of information and comprehensiveness, few works are its equal. As stated by the authors in the preface in the first German edition, their aim was to present as completely as possible, both from a theoretical and practical point of view, the subject-matter of the lectures and course in histology given in the University of Munich. The examination of the work shows that the authors have amply considered the embryological basis in the most lucid and practical way; the purely morphological part is also clearly summed up and in this portion will be found the most recent contributions to the science. Thus the American editor has incorporated the recent studies of Mall on the structure of the spleen; and the nervous system has been equally developed from the standpoint of recent contributions. The value of the book is further enhanced by an excellent introductory chapter on general microscopical methods. Among the English books this takes the first place.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

The History of Medicine in the United States. From the Earliest English Colonization to the Year 1800. By Dr. F. R. Packard, 8vo, 542 pages. Illustrated. J. B. Lippincott Company, Philadelphia and London. $4.00.

Pulmonary Consumption, and Allied Diseases of the Lungs. By Dr. Thomas J. Mays. 8vo, 540 pages. E. B. Treat & Company, New York. $3.00.

Infant-Feeding in Its Relations to Health and Disease. By Dr. Louis Fischer. 8vo, 350 pages. Illustrated. F. A. Davis Company, Philadelphia and Chicago.

A Text-Book of Diseases of the Nose and Throat. By D. Bradenkyle. Second Edition. 8vo, 650 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

ORIGINAL ARTICLES.

PRACTICAL FOOD PRESCRIBING.

BY FLOYD M. CRANDALL, M.D.,

OF NEW YORK;

ADJUNCT PROFESSOR OF PEDIATRICS IN THE NEW YORK POLYCLINIC; CONSULTING PHYSICIAN TO THE CHILDREN'S AND INFANTS' HOSPITALS.

IN presuming to add to the long list of papers upon infant feeding, I disavow at the outset any claim to a new method. I believe, however, that some phases of the subject can be presented more clearly than they have yet been and that a method already devised may be made still more simple, so simple, in fact, that any practitioner can use it without learning complex methods or consulting text-books and formulas. I have tried to put theory aside and tell *how*, not *why*.

The knowledge required by the practitioner to become a good infant feeder is considerable and may be classified as follows: (1) A knowledge of breast milk; (2) artificial foods, their chemical and physical composition; (3) good cow's milk and how it is to be secured; (4) the differences between cow's milk and breast milk; (5) the modifying or adapting of cow's milk to each individual infant; (6) the character of the food required in health and disease.

Breast Milk.—The proposition that the child's natural food should be the standard by which to judge artificial food is too rational to require discussion. Breast milk, therefore, has been universally adopted as that standard. But it may be said that there is no standard for breast milk, for no two samples are precisely the same and no two chemists give exactly the same analyses; true as regards minute precentages, which means that there is no one strength of food provided by Nature for every infant; untrue as regards the fact that all breast milk consists of fat, milk sugar, proteid, salts, and water. Although there are some who differ, the majority of authorities still give the following as the composition of average breast milk: fat, 4 per cent.; sugar, 7 per cent., proteid, 1.5 per cent.

Artificial Food.—Without entering upon prolonged discussion, it is sufficient to say that all so-called infant's foods are deficient in one or all (most of them in all) of the important elements —fat, milk sugar, and proteid. Fat is almost universally lacking, but its importance is evident from its large relative amount in breast milk. Not only are the foods lacking in chemical composition, but they are in large measure derived from vegetable and not from animal sources. The organs of the infant were not designed to digest vegetable substances.

Diluted condensed milk always produces rickets if its use is prolonged, for it is deficient in fat and proteids. A dilution of 1 in 12, the one most commonly used, contains but one-eighth the amount of fat and one-third the amount of proteid of average breast milk. Double that strength contains but one-fourth the proper amount of fat, but the sugar is so excessive as to soon upset the stomach. A food so wide of the standard is not a proper one for an infant. Notwithstanding certain drawbacks, cow's milk, properly modified, is unqualifiedly the best artificial food for infants.

Good Cow's Milk and How It Is Secured.—Notwithstanding all that has been written upon the subject, the profession is not sufficiently awake to the importance of clean milk, nor has the average practitioner studied sufficiently the methods necessary to obtain it. It is the growth of bacteria that renders cow's milk unfit for food. But it is impractical for practitioners to count the bacteria or to judge of the number present by appearances. It has been observed, however, that there is a close relation between the acidity of the milk and the deleterious bacteria. "Milk with the least acid," says H. L. Russell, "as a rule is the freest from spore-bearing bacteria." Taking advantage of this fact, a method has been devised by Farrington by which the acidity of milk may be easily determined by means of alkaline tablets. They are largely used in the dairy industry. A special form of these tablets is now made for the use of physicians and are known as Ideal Milk Testers. By their use the acidity of milk may be quickly tested and its safety as a food may be quite accurately judged.

One of the most important details in the handling of milk is rapid cooling immediately after milking. It is the belief of many competent observers that Pasteurizing is not necessary when adequate precautions are taken against the entrance of bacteria, and the milk is immediately cooled below 60° F. and not allowed to rise above that temperature. In milk that is immediately bottled and cooled, the cream will rise almost completely in four hours. The milk of several cows is better for an infant than that of a single cow, for it will vary less in its composition from day to day.

Milk should be sterilized only in rare instances. It is not necessary to here discuss the objections to sterilization. Milk should be Pasteurized when there is the slightest doubt as to its cleanliness and when it cannot be kept below 60° F. Pasteurizing is designed to accomplish one result and one alone—the destruction of bacteria. It does not render the milk more digestible nor diminish in the slightest degree the necessity for

modifying it. Neither will Pasteurizing destroy poisonous products which have already been formed. It is infinitely better to prevent contamination by proper methods of production and handling than to try to prevent the results. Under present conditions, however, Pasteurizing is often a necessity and has saved thousands of infant lives.

Breast Milk and Cow's Milk.—The proteid of cow's milk is from two to three times greater than that of breast milk. In modifying cow's milk, therefore, the proteid must be reduced by diluting the milk. This reduces the fat and sugar also. Hence fat and sugar must be added. The theoretical problem is simple: Reduce the proteid by diluting the milk; increase the fat and sugar by adding those elements. This process is known as modifying, and is nothing but changing the constituents of cow's milk to make them available for the use of the human infant. Modified milk is not of any particular composition, nor is there any particular modification that suits every infant. It is simply milk adapted to each case. Misunderstanding of this point has been perpetuated by the persistance with which most writers upon feeding have used formulas, supposed to be proper for different ages. Such a course has practically made modified milk nothing more than a series of mixtures. It has prevented the more general acceptance of the method because no practitioner could remember the formulas, and would not carry the books and magazines with him, to be opened and copied every time he wished to prescribe food for an infant. In the quiet of the office such formulas may be useful, but most food prescribing is done in the home of the patient.

What is needed by the general practitioner is a method by which he can successfully prescribe food without the use of books and mathematical calculations. Such a method is at hand and is almost as simple as diluting condensed milk.

Modifying Milk.—It is useless to think of milk as being of a definite composition. It is not. Some is rich and some is poor, but the top nine or ten ounces of cream and skim milk from a quart of any milk contains fat three times the proteids. The top fifteen or sixteen ounces contains fat two times the proteids. Hence between these nine and fifteen ounces, we can get fat anywhere from two to three times the proteids, which is the range in woman's milk. By using a one-ounce dipper, devised by Dr. Chapin, for removing the top milk, twenty-five different ratios between fat and proteids can be obtained from one quart of milk.

The one object in modifying milk is to obtain a mixture upon which the infant will thrive. A pediatric specialist of large experience will find such a mixture more quickly than will a general practitioner with small experience. Specialists have no secret process, however. They try combinations, just as other doctors must. If they have any secret, it is a very open one and may be thus expressed: *Begin on a weak mixture and work up to the point of tolerance.* The average practitioner does precisely the opposite. He begins on a mixture too strong and after weeks of indigestion gradually works *down* to the point of tolerance. He is afraid to dilute the milk sufficiently at the outset.

In the modifying of all ordinary milk, it does not matter whether it is rich or poor, for cow's milk from the same source does not often vary more than does breast milk. The ordinary infant readily tolerates some variation in both breast milk and cow's milk. If we begin with a weak preparation we find what the child can take—and that is successful feeding. We reach that practical result whether the milk be high or low in fat and proteid. We give the child what it can digest and thrive on. We may do this without regard to percentages, though it is better to know as nearly as possible what the strength of each mixture is.

The following table will explain more clearly the statements regarding the proportion of fat and proteids in the upper nine or fifteen ounces of milk and cream. I am well aware that some recent experiments have shown a lower percentage in the seven-ounce cream. Below that, however, all chemists give virtually the same results. It is rare in actual practice that cream stronger than fourteen per cent. is required.

The table is based upon milk containing 4 per cent. each of fat and proteid.

TABLE I.

7	ounces	top	milk	contain	16	per	cent.	fat,	4	per cent. proteid
8	"	"	"	"	14	"	"	"	4	" "
9	"	"	"	"	12	"	"	"	4	" "
11	"	"	"	"	10	"	"	"	4	" "
15	"	"	"	"	8	"	"	"	4	" "
20	"	"	"	"	6	"	"	"	4	" "

These top milks simply require diluting three to ten times. When the milk is to be well diluted, the top 9 ounces are commonly required; as the dilution is reduced, 12 or 15 ounces.

For example, dilute nine-ounce top milk to one-fourth and we have 3 per cent. fat and 1 per cent. proteid. Dilute fifteen-ounce milk to one-half and we have 4 per cent. fat and 2 per cent. proteid. For a young infant, dilute nine-ounce top milk eight times and we have 1.5 per cent. fat and .5 per cent. proteid. With the same dilution, if we take off two ounces less (seven-ounce top milk), we have 2 per cent. fat and the same proteid. Take two ounces more (eleven-ounce top milk) and we have 1.25 per cent. fat and the same proteid. We thus regulate the proteid by diluting; the fat, by the amount taken from the top.

Simply divide the figures of this table by the number of times the milk is diluted and the percentages of fat and proteid in the mixture are known. The claim is not made that this will result in the same absolute percentages with every milk. No modification can possibly do that, unless the quality of the milk is known. It will, however, be as accurate as any other method of home modification and will be sufficiently close

for ordinary cases. Systems of formulas based upon average milk are certain to fail in many cases because all milk is not average. While it is desirable that the practitioner should know just what percentage the infant is getting, he can prescribe satisfactorily if he will but begin low and work up slowly by taking gradually less from the top of the milk or diluting it less, thus changing the fat or proteid as he desires.

If the whole amount of top milk is not required, it should still be dipped off. The portion not required may be returned to the bottle. For example, if the child is to have 24 ounces of food, of which one-fourth is to be nine-ounce top milk, we use 6 ounces of the latter and return 3 to the bottle. This point must be carefully explained to the mother, or she may take off but the six ounces required, thus increasing the amount of fat by 50 per cent.

The Sugar.—Having obtained the requisite percentage of fat and proteid, we must add sugar. The accuracy of the following figures is evident at a glance:

TABLE II.

1	part	sugar	to	20	parts	food	adds	5	per	cent.
1	"	"	"	25	"	"	"	4	"	
1	"	"	"	33	"	"	"	3	"	
1	"	"	"	50	"	"	"	2	"	

This renders the problem very easy, but still easier is the fact, recently pointed out by Holt, that for mixtures below 2 per cent. of proteids (those less than half milk) one ounce of sugar to 20 ounces of mixture, with the sugar already in the milk, will give a total of from 6 to 7 per cent. of sugar. These are the percentages required in almost every formula for the first ten months.

An ounce measure will hold two-thirds of one ounce of milk sugar by weight. If measured by a tablespoon, two level tablespoonfuls of granulated sugar or almost three tablespoonfuls of milk sugar equal one ounce. Milk sugar should be used when possible. When cane sugar is used, the percentage should not be as great as for milk sugar, for the child does not usually digest it as well.

Diluent.—Three forms of diluent are in common use, boiled water, plain gruel, and digested gruel. There has been more discussion on the subject of diluents during the past two years than upon any other question in infant feeding. Some strongly oppose the use of anything but water, using chiefly the argument that in employing a gruel, we are introducing an element into the food not found in breast milk. This argument loses its force when we remember that in the nitrogenous elements of cow's milk we have substances not found in breast milk. The decision should be based upon experience rather than upon theory. If gruels aid in digesting the proteids of cow's milk, no theory should be allowed to prevent their use. My personal experience is that many children do perfectly well with water as a diluent, while others digest better when a predigested cereal is added. Digested gruels are certainly more effective than plain gruels. They are certainly now used much more largely than they were a few years ago by nearly all leading pediatric practitioners. These gruels are made from oatmeal, rice, barley, or wheat flour. A heaping tablespoonful is made into a gruel with a pint of water by boiling for fifteen minutes. The gruel is allowed to cool to about 130° F., when a teaspoonful of Cereo is added, which converts the starch into absorbable dextrin and maltose. Sometimes one cereal agrees with an infant better than another. The object of the digested gruels is not so much to add nutriment to the food as to render the caseine more digestible.

Percentage Feeding.—By this term we mean nothing more in ordinary food prescribing than a method of measuring the strength of our mixtures. In laboratory feeding alone, do we write our prescription in percentages. In home modifying we write our prescription as a formula, but we do not know what we are giving unless we know its percentage strength. It is the only means of accuracy. Still percentage feeding has been made an unnecessary bugbear to most physicians who regard it as an intricate and cumbersome contrivance.

By the method of modifying just described, we can readily obtain any percentages, if we wish to begin with a percentage prescription. As the ordinary range of top milk required is between 8 per cent. and 12 per cent., we can take three items from the table already given as a working table, as follows:

TABLE III.

9	ounces	top	milk,	12	per	cent.	fat,	4	per	cent. proteid.
11	"	"	"	to	"	"	"	4	"	"
15	"	"	"	8	"	"	"	4	"	"

These few numbers are all that are necessary to enable one to obtain a given strength of milk. The one source of error is the varying strength of different milks and that applies to every method of home modification when we try to make a mixture that will contain definite percentages.

Suppose we wish to make a mixture containing fat, sugar and proteids in the proportion of 4, 7, 2. To get 2 per cent. of proteid, we must divide the 4 per cent. proteid of top-milk by two. We then require a top milk containing twice the amount of fat desired, or 8 per cent. This we obtain by taking fifteen-ounce top milk and diluting it to one-half. That is, we divide the proteid by two and multiply the fat by the same number. Suppose we wish a mixture of 2, 6, 0.8. To obtain 0.8 per cent. of proteid from 4.0 per cent., we divide by five and must, therefore, take a top milk containing the fat five times as strong, or 10 per cent. Take, therefore, eleven-ounce top milk and dilute it to one-fifth. The sugar in each case should be one ounce to 20 ounces of the mixture.

I have purposely refrained from giving formulas. They are a detriment and a drawback to the practitioner and serve no useful purpose in

ordinary home prescribing. They are useful for reference in cases of difficult feeding and may be found in abundance in the text-books of Rotch and Holt. For ordinary practice a less cumbersome method is necessary.

Character of the Food Required.—The policy of beginning feeding with a weak mixture should not be misinterpreted. The infant should not be kept on such a diet. The strength should always be slowly but steadily increased. On the second day of life an infant can usually take nine-ounce top milk diluted eight times, to be increased after the fourth day. For an older child nine-ounce top milk may be diluted from five to seven times at the outset. One important fact has been demonstrated by experience—few children under six months can take cow's milk in the strength of average breast milk.

Having found a satisfactory food, it is not advisable to change upon slight provocation or to try to meet every little symptom by changing the formula. If the child becomes acutely ill it is best to dilute, so as to reduce all the elements. If the illness is indigestion or diarrhea, stop milk at once and completely. Roast beef is an excellent article of diet for healthy adults, but very inappropriate when they are suffering from vomiting or diarrhea.

Summer diarrhea should not be considered a simple indigestion, but a poisoning by bacteria which thrive particularly well in milk. Even in simple indigestion, it usually saves time and trouble to stop the milk for a few feedings and give broth or digested gruel, just as one would stop the ordinary diet of an adult. Restlessness at night is commonly due to indigestion, and may frequently be cured by making the last feeding of digested gruel.

Chronic indigestion, with beaded ribs and sweating of the head in sleep, suggests rickets and indicates more fat and perhaps proteid.

Painful joints and purple gums suggest scurvy and indicate a diet of fresh, unheated milk with, perhaps, beef-juice and orange-juice. Eczema in young babies is sometimes relieved by reducing the fat. Constipation with hard, dry stools may sometimes be relieved by increasing the fat, but caution should be used against increasing it excessively. Colic, flatulence, and restlessness are an indication for the reduction of the percentage of proteids.

Regurgitation of the food with perhaps small frequent passages, suggests excessive fat and indicate its reduction. Green, acid stools, with perhaps gas and colic, suggest an excess of sugar. Curdy stools call for more dilution of the top milk. Foul stools call for bowel washing and reduction or stopping of the milk.

It is rare that symptoms of indigestion can be completely relieved by reducing any single element. It is usually best to reduce all for a time and slowly work up using particular care with reference to the element that is apparently the offender.

STUDIES IN THE BACTERIOLOGY OF TYPHOID FEVER, WITH SPECIAL REFERENCE TO ITS PATHOLOGY, DIAGNOSIS AND HYGIENE.

BY PHILIP HANSON HISS, JR., M.D.,
OF NEW YORK;
INSTRUCTOR IN BACTERIOLOGY AND HYGIENE, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, N. Y.

The discovery and interpretation of the exact bacteriological conditions and pathological lesions existing in the various stages of typhoid fever have for years occupied the attention of investigators. Patient observation and careful experimentation have brought much to light in regard to these conditions and lesions. Nevertheless, in the case probably of no other disease, the inciting organism of which has been so definitely determined and thoroughly studied in pure culture, has so much of the experimental work proved unsatisfactory and interpretation been so hampered by untrustworthy data.

This, I take it, has depended largely upon two sets of conditions underlying these investigations and experiments; in the first place upon the slight susceptibility of the usual test animals to a true typhoid infection, the levity of the lesions induced by such infection or intoxication, and the lack of conformity between the disease process in these animals and that occurring in man, having of necessity left much in doubt and permitted of different interpretations.

In the second place this has depended upon the close similarity of the colonies of the typhoid bacillus to those of the various bacilli belonging to the so-called colon group when these bacilli are grown upon nutrient pepton-gelatin and pepton-agar. That these media should have been those in universal use as separating and isolating media must, as far as the bacteriology of typhoid fever is concerned, be looked upon as unfortunate, since it not only placed an almost insuperable barrier in the way of recognizing typhoid colonies in the presence of those of colon bacilli, but at the same time brought into undue prominence practically the sole important characters which typhoid and colon bacilli have in common.

The similarity of colony characters and the occurrence of colon bacilli normally in the intestinal tract, and at times in various organs after death, so that typhoid and colon colonies often appear in company in the isolating media, have given rise to endless confusion in the bacteriology and interpretation of typhoid fever. Further than this, upon these points—the similarity of colony appearances and the identity of place of occurrence—have been largely based the idea of the close relationship and even interchangeability of these probably phylogenetically connected, though really very distinct and easily differentiated forms—a relationship which would undoubtedly have been long in suggesting itself had some other medium been at the command of those investi-

gating the subject, or had the colon bacillus not been a regular dweller in the intestine.

The object of the present paper, therefore, is to pass in review the bacteriological investigations of typhoid fever which have been based on a fuller knowledge of the bacillus, and to see what bearing the results of these investigations may have on our interpretation of the disease process in man, and for what aid in diagnosis we may legitimately turn to bacteriology and what assistance hope for in determining rational hygienic measures for limiting the spread of the disease.

The history of the typhoid bacillus from the moment of its ingestion to its appearance in various regions and organs of the body still presents many gaps and on many points we cannot yet speak authoritatively, hence conclusions which may be drawn in this paper are in many instances tentative and are here simply set forth as the most probable in the light of present statistics and with the desire to focus attention upon and incite further investigation on mooted points.

A detailed résumé of the various investigations which have been carried on since Eberth's[1] discovery in 1880 of the typhoid bacillus in the tissues of those dead of typhoid fever, and Gaffky's[2] communication in 1884 in regard to the isolation of this bacillus in pure culture on artificial media, would be beyond the limits of this paper, but a few words on etiology may be of value, since the etiological relationship of this bacillus to the disease is in some of its phases particularly difficult of demonstration. This, as has been said, is especially true of animal experimentation, for although the typhoid bacillus and its products when introduced intravenously, subcutaneously, or intraperitoneally, do bring about the more or less rapid death of certain animals, still it has been observed that it is practically impossible by such means to induce the characteristic intestinal tissue reactions and lesions. Some observers even have held that a true infection, implying a multiplication of the organisms within the animal body, does not take place, and that the animals simply succumb to an acute intoxication due to the absorption of the already manufactured toxins and products introduced with the bacilli, and to the poisons liberated from the bodies of the bacilli, as they die and disintegrate within the inoculated animal.

It is generally true that death from such inoculations takes place in most animals within a limited number of hours, or not at all, and if a true infection does occur its rapidly fatal termination practically precludes the appearance of such characteristic and advanced pathological changes as those induced in man by the presence of this organism. Notwithstanding these facts, an infection giving rise to some of the more typical lesions, it seems, may at times be induced by the usual means or may be brought about with greater regularity by various methods which are used either to raise the virulence of the organism experimented with, or to reduce the insusceptibility and resistance of the animals inoculated. Sanarelli,[3] who has contributed to the knowledge of the action of this organism and its poisons on the animal economy and in regard to the distribution of bacilli within the animal body, considers that under proper conditions a true infection takes place and that the sites and character of the lesions induced, either by a true infection or the introduction of the products of the macerated organisms, are in many points peculiar to the infection or poisoning, and have a close similarity to those incited in man; close enough in fact to form a strong link in the proof of the etiological relationship of this bacillus to typhoid fever.

From time to time, cases have been reported of typical intestinal ulceration following inoculations of typhoid bacilli in animals, and lately Remlinger[4] seems to have had little difficulty not only in inducing these typical lesions in the intestines of rats and rabbits, but in bringing about infection by ingestion. Rare cases of infection by ingestion or by the intestinal tract have been reported, but special means have been used to destroy the action of the acid of the stomach, or to introduce the bacilli into the intestine. Ordinary feeding with infected food has heretofore proved ineffectual, and Remlinger's success not only in this line, but in the observation of typical lesions, is to say the least exceptional, and probably will be hesitatingly accepted unless further experimental confirmation is given it.

The demonstration of these rarer and more characteristic pathological lesions in animals, taken in connection with Pfeiffer's discovery of the action of special bactericidal substances—the so-called bacteriolytic or lysogenic substances—which develop in the blood of typhoid-fever patients and of animals undergoing immunization, and in connection with the recognition by various observers of other characteristic changes in the blood of typhoid patients and animals, changes supposedly due to the development of substances known as paralysins and agglutinins, which give rise to the phenomena now so familiar to us as constituting the Widal serum reaction, places the relation of the bacillus to the disease on a more scientific basis, although the constant presence of this organism in the organs of typhoid cadavers and its frequent isolation from the blood and spleen, as well as from the feces and urine of typhoid-fever patients during life, render these further proofs almost unnecessary.

The greatest and real obstacle, however, to a true appreciation and comprehension of the typhoid process in man, lay not so much in the question of the pathogenicity or non-pathogenicity of the typhoid bacillus for animals

and the failure of the typical disease process to unfold itself in them, as in the difficulties encountered in the isolation and identification of the typhoid bacillus in the presence of other forms of bacteria. This, as has been previously suggested, and as we shall see in considering the question more closely, has given rise to various conceptions of the disease process and in regard to the localizations of the bacilli in the body.

Until about 1890, the characters of growth and the chemical reactions depended upon to differentiate typhoid bacilli from various members of the so-called colon group of bacilli were too few and ill defined for complete confidence to be placed in statistics based upon them. It was only with the application of methods bringing to light the more obscure physiological activities of the typhoid and colon bacilli—especially the results of their life processes in the presence of the various sugars, and the changes brought about in media containing pepton, *i.e.*, indol production—that statistics relating to the isolation of typhoid bacilli from various sources could be used with confidence. The confusion existing in regard to the typhoid and colon bacilli, which was primarily due to the close resemblance of their colonies on the ordinary isolating media, led, before the recognition of the colon bacillus by Escherich,[5] to the general belief that the typhoid bacillus occurred in great numbers in the intestinal contents, and to the conception of the disease as a more or less pure intoxication, in which the bacterial products were to a large extent manufactured by these organisms in the intestinal lumen, and from there absorbed, thus giving rise to the symptoms and lesion characteristic of typhoid fever, with a later local invasion of the lymphatic tissues and patches of Peyer by the bacilli. After Escherich's discovery and the consequent evolution of the more definite tests for the recognition of these bacilli in pure culture, it was found to be possible only rarely and with difficulty to isolate the typhoid organism from the intestinal contents. As an instance of this we may mention that, even as late as 1895, we find Wathelet[6] investigating stools by plating out in ordinary nutrient gelatin and recording very discouraging results, only ten colonies out of the six hundred tested proving to be those of typhoid bacilli. This experience is typical of that of many other investigators, who have interested themselves in the isolation of typhoid bacilli from intestinal contents and from the organs of those dead of typhoid fever. Such failures as these lent support to the opinion that the inciting organisms were not, at least as a rule, to be found in the feces, and to such statements as that of Silvestrini[7] that the tumefaction of the patches of Peyer ought not to be looked upon as due to a primitive localization of the virus, but as a local expression of a general process. Sanarelli,[8] like Silvestrini, laboring under this misconception in regard to the presence of the bacilli in the feces, believed the lesions to be due to the toxins formed at other places in the body by the bacilli, these bacilli thriving best in the lymphatic system and there producing toxins which besides causing phenomena common to many other poisons, induce lesions characteristic of typhoid fever; and further, he considered that in experimental typhoid fever and, as he thought, in the typhoid fever of man, the intestinal lesions were induced exclusively by toxins produced elsewhere in the system, and that this alleged fact took away all value from the old idea according to which typhoid fever should be considered as an infectious process of intestinal origin with localizations in the intestines.

The conclusions of these and other observers, reached in regard to the essentially general character of the typhoid infection, in contradistinction to an intestinal intoxication, or even an infection with its seat solely in the intestinal lymphatic tissues, should, as we shall see, be looked upon as substantially correct, although recent methods for isolating typhoid bacilli have enabled us to demonstrate that these investigators were distinctly wrong in supposing that typhoid bacilli occurred only rarely or not at all in the intestinal contents of typhoid fever patients.

How far the statistics at our command coincide with these views and are suggestive of the seats of election or rather existence of the organisms in the body will be briefly considered later under various headings.

The questions which will be taken up primarily are those relating to the possibility of isolating the bacillus from various situations during the disease, and the diagnostic value of such isolations to the clinician, and also the hygienic as well as clinical question of the usual time of appearance and disappearance of the organisms from the intestinal contents and urine.

In the various bacteriological studies of typhoid fever for diagnostic purposes attempts have been made during the life of patients to isolate the bacilli by spleen puncture and from the blood, rose-spots, sweat, urine, feces, and throat and mouth secretions and exudates. The principal results of these investigations it may be profitable to consider in some detail.

Spleen Puncture.—Typhoid bacilli have been frequently isolated from the spleen by puncture during life. The usual time of their first appearance in this organ cannot be determined from present statistics. That they are very constantly present in the spleen during some period of the disease does not admit of doubt, but whether they arrive there practically at the inception of the disease and whether the spleen then acts as a safe place of abode and

multiplication have not been proven. Isolations from about the seventh or eighth day on do not seem to be uncommon.

The scientific evidence to be obtained of the distribution of typhoid bacilli throughout the system, especially of the usual time of arrival of the bacilli in the spleen, as well as the value of the results from a diagnostic standpoint, makes spleen puncture a very tempting procedure to the pathologist and bacteriologist as well as to the clinician, yet, as a means of diagnosis and investigation, it is not to be encouraged on account of the grave consequences to the patient which its employment sometimes entails.

Blood and Rose-Spots.—The earlier examinations of the blood and rose-spots of typhoid patients proved in the main unsatisfactory, though in spite of many failures, some of the investigations gave a certain proportion of positive results. In 1895, Thiemach[9] investigated seven cases with the recovery of the bacilli in four of them, three from the rose-spots and one from venous blood. In plates made from these blood specimens the number of colonies was very small, never more than two or three developing. With Besson[10] the drawn blood from nineteen cases gave no organisms and the result of the investigation of fifty-four rose-spots from nineteen patients showed fifty-three negative and only one positive result. Scottmüller[11] examined the blood from fifty patients, and obtained typhoid bacilli from forty of them. He made plates with about 4 c.c. of the blood mixed with agar. The colonies, by this method, were few in number and very tardy in development. Castellani[12] used large quantities of bouillon, which he inoculated with 10-40 drops of the blood to be examined. By doing this the blood was highly diluted and its germicidal action weakened. Fourteen cases were examined with twelve positive results. Auerbach and Unger, using practically the same technic, took blood asceptically from the median vein, and added 10, 20 and 30 drops to 300 c.c. of bouillon in Erlenmeyer flasks, which were then well shaken. They thus demonstrated bacilli in the blood of seven out of ten patients. Of the seven positive cases only one ran a severe course and terminated fatally. The remainder were either light or of medium severity. The bacilli were present in three cases on the twelfth day, in one on the sixteenth, and in one on the twenty-second. In two cases, during relapses with the development of rose-spots, they were found on the twenty-ninth and forty-second day respectively.

Neufeld[13], in 1899, believing that the failure of the investigations of rose-spots was due to the germicidal action of the blood accompanying the bacilli from the spots, instituted a procedure in which this blood was immediately diluted by its addition to nutrient broth. This method appeared to be eminently successful since he was enabled to cultivate the organisms from thirteen out of fourteen patients thus examined. Curschmann[14], subsequently following the same method, obtained the organism from fourteen out of twenty patients, and in none were more than two spots incised. Richardson[15], of Boston, with a slight modification of Neufeld's method, has been successful in the isolation of typhoid bacilli from five out of six patients. In his procedure, after a preliminary washing with alcohol and ether, the rose-spots are frozen by a spray of ethyl chloride. This not only makes the operation painless, but drives the blood out of the skin and away from the vicinity of the spot. A small incision is made over the spot and some of its contents curetted out with a very fine skin curette and transferred to a tube of nutrient broth, and finally the blood collecting as the effects of freezing wear off is transferred to broth.

These researches show that the organism may be obtained in this way as early as the seventh and eighth days, and apparently generally several days before the outspoken development of the substances in the blood which give rise to the Widal reaction. Unfortunately, for the general use of these procedures, five or six spots, it seems, should be examined in each case to insure success, and the curetting of spots is an operation which will undoubtedly be submitted to with much hesitation by the majority of patients.

Mouth and Throat.—Besson[16] has called attention to the examination of the products of inflammation from the throats and especially the tonsils of patients suffering with typhoid fever, and reports the recovery of typhoid bacilli from the tonsils of six out of ten cases investigated; he lays stress on a fact, most obvious from his results, that the expectoration of such patients may contain the specific organism and ought to be carefully disinfected. Comparatively little attention has been paid to the bacteriologic examination of mouth and throat secretions in typhoid, but such results make these investigations seem very advisable from both a diagnostic and hygienic standpoint.

Urine.—The examination of the urine of typhoid patients has heretofore given a greater number of positive results than the blood and the percentage of these results has not become lower as the methods used for the recognition of typhoid bacilli have grown more exact and refined. Neumann[17] discovered the bacilli in eleven out of forty-six cases and Karlinski[18] in twenty-one out of forty-four cases. Seitz, Konjajeff, and Silvestrini, also record positive results. In 1895, Wright and Semple[19] reported six positive cases out of seven. Besson, writing in 1897, analyzed thirty-three cases examined by him. All of his specimens of urine were carefully tested to determine the presence or absence of albumin and the proportion in which it occurred. The urine from nine patients did not show albumin, nor

were typhoid bacilli isolated from these specimens. Twelve of the patients gave albumin in traces and always in amounts less than 1 gm. per 1,000 c.c. Among these latter only one gave a positive result. The urine from the remaining twelve patients contained albumin in large amount, 1 gm, or more per 1,000 c.c., and five of the cases showed typhoid bacilli. From his researches, Besson concluded that the bacillus of Eberth appears in the urine only when it contains albumin, and especially in quantities equal to or above 1 gm. per liter, and that the bacilli disappear from the urine at the same time that the albumin disappears. Karlinski also noted the relation existing between the occurrence of the bacilli and the presence of albumin.

The researches of Petruschky,[20] Richardson,[21] and Horton-Smith[22] indicate that the bacilli do not appear in the urine before about the fifteenth day of the disease or even later in the febrile period and at times not until convalescence is established. From the fifteenth day on, general statistics show that the bacilli may be isolated from about 25 per cent. of the cases. The organisms according to most observers may persist in the urine for days, weeks, and in rarer cases it has been claimed for months. Albumin is generally present in these urines, but, it seems, may in rare instances be absent; on the other hand, urine may contain albumin but no bacilli.

My own results present a fair agreement with these conclusions. Seventy-five supposedly true cases of typhoid fever* examined before the fourteenth day did not once yield typhoid bacilli in the urine.

Another special series of fifty-four patients (104 specimens of urine) examined in the later stages of the disease, from the twenty-second day to the tenth week, show the presence of the bacilli in seven.† In these fifty-four patients the temperature was reported to have reached normal and convalescence was established. The results of the examinations of the seven positive cases, being of special interest, are here recorded.

Case III.—Urine examined on the twenty-fourth and thirty-third day. Bacilli isolated from both specimens and albumin found to be present.

Case V.—Examined once in fifth week; bacilli present, also albumin.

Case XVI.—Examined once, on thirty-sixth day; albumin could not be determined.

Case XIX.—Reported as in the sixth week. October 13th, urine did not contain bacilli. Albumin ¼ gm. to 1,000 c.c. On October 18th, 19th, 25th, and November 1st, bacilli were present. Albumin had disappeared on November 1st and the bacilli were not found on November 7th, 14th, 16th, 22d, or December 1st.

Case XXXVII.—Bacilli were present in the urine, but no albumin, at time of the first examination, October 25th (fifth week). On November 4th, no albumin was present and no bacilli, and again on November 9th and 17th neither bacilli nor albumin could be demonstrated.

Case XLV.—Exact day not recorded, but case convalescent. November 19th, bacilli and albumin present; December 3d, no bacilli and no albumin.

Case LIV.—Seven and one-half weeks. Convalescent. Pus in urine, and organisms exceedingly numerous. Urine not further examined. Patient later developed periosteal abscesses.

The examination of these fifty-four patients seems to indicate that possibly twelve or more per cent. of cases in which the temperature has touched normal may be looked upon as containing typhoid bacilli in the urine, and the histories indicate strongly that the bacilli tend to disappear as the albumin vanishes. This vanishing with the albumin may be more frequent in post-febrile stages at which time the supply of bacilli from the general system to the kidneys and bladder has presumably ceased, and the bacilli not being supplied with suitable nutriment in the urine cease to multiply and are eliminated from the bladder.

The investigation of the urine, in the light of the foregoing conclusions, is seen to be of more value from the hygienic standpoint than from that of diagnosis. Except in persistently obscure cases when later examinations may be useful, the examination of the urine for purposes of diagnosis is apt to be futile, on account of the usual late appearance of the organisms in this excretion.

Fæces.—As I have previously indicated, the problem of isolating the typhoid bacilli from the stools of typhoid patients had, up to the time of the introduction by Elsner[23] of his modification of Holz's acid-potato-medium,[24] remained to such an extent unsolved, that Nicolle[25] even went so far as to remark that not only in water, but also in the stools, and even in the parenchyma of the spleen, the presence of the bacterium coli constitutes an insurmountable obstacle to the isolation of the typhoid bacilli. Although this was hardly a fair statement of the case, yet taken in connection with such experiences as those of Wathelet, previously noted, it gives some idea of the difficulty of recognizing the colonies of bacillus typhosus in the usual gelatin plates, when these colonies are surrounded by those of the constant inhabitants of the digestive tract—the members of the colon group of bacilli. This is not the only difficulty attending the use of ordinary gelatin, for organisms at times occurring in the plates possess the power of liquefying the gelatin, before a typical development of the typhoid colonies can take place. By Elsner's method, in which a potato-extract gelatin medium plus 1 per cent. potassium iodide is used, these liquefying species are to a great extent ruled out, and in the majority of cases the colon bacilli and typhoid organisms alone develop. By this method the typhoid colonies according to most observers may be recognized in from forty-eight to seventy-

* Some of these cases may not have been typhoid-fever cases. Exact data could not be obtained in all instances.

† I am indebted to Dr. Edmund Le Roy Dow for valuable assistance in procuring many of these specimens, and for the albumin determinations.

two hours, being much smaller and lighter in color than those of the colon bacilli. This medium, not only in the hands of Elsner, but also when applied by Brieger, Lazarus, Chantemesse, and others in Europe, and by Richardson in this country, has given very satisfactory evidence of its usefulness. By this method of Elsner, Brieger[26] investigated the stools from eleven patients with typhoid during the various stages of the disease and claimed positive results in all the cases in the febrile stage. Examinations made just at the time of the disappearance of the fever and during convalescence gave uniformily negative results, with the exception of two cases in which a relapse occurred, and in one case complicated by venous thrombosis. Lazarus,[27] by Elsner's method, examined the feces of twenty-one patients, five in the febrile stage, and sixteen convalescent, free from fever for a longer or shorter time. In the febrile cases from the first to the third week he repeatedly found the bacilli. In cases convalescent, three days to six weeks, only three were shown to contain bacilli. One, it is thought, gave the bacilli on the forty-first day of convalescence. Chantemesse,[28] likewise, examined by the same method the stools of sixteen patients who were suffering from or had had typhoid fever. Three times the examination was negative; once in the case of a young patient three weeks convalescent, and with two others in the febrile stage. His other cases he claims gave positive results as early as the seventh and as late as the twenty-sixth day. Chantemesse considered the slowness of the development of the typhoid colonies a serious inconvenience in the method of Elsner, so valuable in other respects, and expressed the hope that a perfecting of the method would render it more available for purely clinical purposes.

In April, 1896, investigations were commenced by me on the behavior of various bacteria in semi-solid culture media. These media gave such promise of being useful in the differentiation of closely allied forms of bacteria that the study of bacillus typhosus and the various members of the colon group of bacilli was undertaken because of the interest and practical value connected with the differentiation of these organisms. These investigations are elsewhere recorded in detail (*Journal of Experimental Medicine*, 1897, Vol. II., No. 6, p. 677) so that I now only call attention to the composition of the media resulting from the experiments, and to the results of the practical application of the media to the isolation of the typhoid bacilli from the stools of typhoid patients. Two media are used—one for the differentiation of the colonies of typhoid bacilli from those of the colon group by plate culture, and one for the differentiation of these forms in pure culture in tubes.

The plating medium is composed of 10 gm. of agar; 25 gm. of gelatin; 5 gm. of sodium chloride; 5 gm. of Liebig's extract of beef; 10 gm. of glucose, and 1,000 c.c. of distilled water. The final titration of this medium should indicate the presence of 2 per cent. of normal acid,* phenolphthalein being the indicator, and the medium should be brought to this acidity by the addition of normal hydrochloric acid solution.

The growth of the typhoid bacilli in plates made from this medium gives rise to small light greenish colonies with irregular outgrowths and fringing threads. The colon colonies on the other hand are much larger, and, as a rule, are darker and do not form threads. This medium is practically solid and the differentiation seems to depend upon the fact that typhoid bacilli form threads in a medium of this acidity when pepton is absent.

The tube medium contains agar, 5 gm.; gelatin, 80 gm.; sodium chloride, 5 gm.; Liebig's extract of beef, 5 gm.; glucose, 10 gm.; distilled water, 1,000 c.c., and should react 1.5 per cent. acid, phenolphthalein being the indicator.

In this semi-solid medium the growth of the typhoid bacillus produces uniform turbidity, at 37° C. within eighteen hours. The colon cultures do not give the uniform clouding and present several appearances, dependent upon differences in the degree of their motility, and upon their power to produce gas in the medium.

The usual method of making the test is to take enough of the specimen of feces, *i.e.*, from one to several loopfuls, and transfer it to a tube containing broth, making the broth fairly cloudy. From this emulsion five or six plates are usually made by transferring one to five loopfuls of the emulsion to tubes containing the melted plate medium, and then pouring the contents of these tubes into Petri dishes. These dishes, after the medium has hardened, are placed in an incubator at 37° C. and allowed to remain for eighteen to twenty-four hours, when they are ready for examination. If typical colonies with fringing threads and outgrowths are found, the tube medium is inoculated from them and placed in the incubator at 37° C. for eighteen hours. If these tubes then present the characteristic clouding, our experience indicates that the diagnosis of typhoid may safely be made, *for the bacillus of typhoid alone, of all organisms occurring in feces investigated during these experiments, has displayed the power of giving rise both to colonies with fringing threads in the plating medium and the uniform clouding in the tube medium when exposed to a temperature of 37° C.*

A diagnosis may thus be made in from thirty-six to forty-eight hours. If doubt is entertained as to the distinctiveness or value of these characters, the bacilli may be further tested against a dilution of a known typhoid serum.

The organisms isolated in this manner have been subjected to the usual tests for the recognition of typhoid bacilli in pure culture, and have always corresponded in their reactions to those given by the typical bacillus typhosus.

By this method, since June, 1897, some three hundred and twenty-three cases, represented by

* Experience has shown that a final reaction of 1.8 per cent. acid is to be preferred, when attempting to isolate typhoid bacilli from feces.

over four hundred stools, have been investigated. Many of these specimens sent by practitioners to the laboratory represented cases in which an early clinical diagnosis could not be made, and which cases were eventually diagnosticated as other affections. Of the three hundred and twenty-three cases, one hundred and eighteen may be considered positively as cases of typhoid fever. Typhoid bacilli were isolated from the stools of forty-five of these cases and their presence could not be determined in seventy-three cases. Among the seventy-three cases giving no typhoid bacilli are to be found ten convalescents, in the feces from which we would not expect to obtain the organisms, and which may therefore legitimately be subtracted in estimating the percentage in these cases. We have, then, practically a series of one hundred and eight cases represented by forty-five positive and sixty-three negative findings, or a positive percentage of nearly forty-two. This percentage must be considered very encouraging considering the unfavorable conditions under which some of this work was carried on.* It is worthy of note, in connection with what will be said later, that at least one-half of the negative results here recorded were represented by specimens of feces taken very early in the disease.

The most interesting results, and those which give a fairer idea of what may be hoped for in carefully investigated cases, were obtained in the examination of stools from typhoid-fever patients of the New York Hospital.†

This series consisted of twenty-six cases of typhoid fever, twenty-one in the febrile stage and five convalescent. Of the febrile cases nineteen were thoroughly investigated and in the feces of seventeen of these typhoid bacilli were demonstrated, and often in great number. Thus of these nineteen cases we find 89.5 per cent. giving positive results. In the other two cases of the febrile series the plates were not satisfactory, and only one specimen from each was examined, both of the patients dying very early; yet including these cases the statistics still show that over 80 per cent. of the febrile cases gave the typhoid organisms. The bacilli were isolated from these cases as early as the sixth day and as late as the thirtieth day, and in a case of suffering from relapse on the forty-seventh day of the disease and nineteenth day of the relapse.

The convalescent cases gave uniformly negative results, the earliest examination having been made on the third day after the disappearance of the fever. The bacilli occurred most regularly in the stools from about the tenth or twelfth day. This was especially well shown by one case examined every two days from the fourth day of the fever, no bacilli appearing until the twelfth day.

Among my cases there have been several in which no Widal reaction could be demonstrated but the feces contained typhoid bacilli and in one case the bacilli were found at the first trial on the tenth day of the disease, three examinations for the serum reaction having proved negative. In this case the specimen examined was not much more than a trace of the intestinal discharge, dried on a splinter of wood, this having been forwarded to me from a neighboring city. The colonies of typhoid bacilli developing in the plate were extremely numerous.*

The foregoing is a review of investigations and statistics from the more purely utilitarian standpoint of diagnosis, but we may now consider more particularly what these researches have brought to light in regard to the history and distribution of the bacilli in the human body, and in regard to their relation to the lesions of the disease.

Typhoid fever can no longer be looked upon, if in fact it really was ever so considered, as a simple toxemia, with the inciting organisms living, multiplying, and producing their toxins, solely in the lumen of the intestine during at least the major part of the disease, with a local invasion of the lymphatic tissues at the time of the appearance of the intestinal lesions, and a probable final general distribution of the invading organisms at the time of or just preceding death. It is now known that the bacilli are to be found in the blood, rose-spots, spleen and urine during the life of the patient, and this often at a fairly early day, and the growing tendency is to interpret the intestinal and other lesions rather as manifestations of the action of diffusible toxins and other products which are produced by the metabolism of the bacilli, or liberated from their degenerating and disintegrating bodies, within the body of the patient, and not of necessity absorbed from the lumen of the intestinal tract—that, in short, the infection is not comparable to cholera. From the standpoint of human pathology, in support of this

* The majority of these specimens were met with in public diagnosis work carried on at the Research Laboratory of the Department of Health of New York. It was, of course, impossible to supervise the collecting of material from the patients, and it must be borne in mind in considering these statistics that, besides disinfected specimens (which are left out of the calculation), many of the other specimens were in what seemed very bad condition when received, often having been delayed several days in transit. With the exercise of due care on the part of the nurse in collecting specimens, and the immediate forwarding of these to the place of examination, much more favorable results may be looked for by those seeking this aid in diagnosis.

† Thanks to the constant courtesy of Dr. Samuel W. Lambert, Visiting Physician to the Hospital, and of Dr. Adrian V. S. Lambert, House Physician, specimens were taken under the most favorable conditions and sent to the laboratory without delay. I wish here to express my appreciation of their kindness, and the interest they have shown in forwarding these investigations.

* These statistics were given in a paper entitled "Studies on the Isolation of Bacillus Typhosus as a Means of Diagnosis of Typhoid Fever," read before the Section on General Medicine, at the New York Academy of Medicine. This paper was not published, but a report of it appeared in the "Medical Record," December 11, 1897.

The following conclusions were at that time drawn:

1. The presence of the "specific" bacilli in the blood, spleen, rose-spots, and urine, and this often early in the disease, indicates that the bacilli occur more generally distributed throughout the body than was at first supposed, and, if we are warranted in drawing any conclusions on this point, the bacilli after their ingestion, seem to invade the system and increase there, not reappearing in the contents of the intestinal tract in great numbers, until probably the time of the breaking down of the intestinal lesions.

2. The stools of typhoid patients have been shown, through the methods at our command, to contain the bacilli in a large percentage of the cases, throughout nearly the entire febrile period.

3. The tendency is for the bacilli to disappear rapidly with the fall of the fever, and in cases in which they do persist, there seems to be an especial liability to relapse.

4. Finally, compared with the Widal test as a means of diagnosis, the recovery of the bacilli may be assumed to positively demonstrate the infection, while the serum reaction may be absent or may indicate a past or present infection, and when present is even then not always to be relied upon as "specific."

view, it is to be noted that cases of typhoid fever in man are reported with no intestinal ulcers, and even without lesions, and the bacteriology of the feces also seem to indicate that these cases exist and are not extremely rare. The few cases of this description which have reached the autopsy-table also offer on their side an explanation of the absence of the bacilli from the feces of clinically typical cases, in which repeated examinations have been made and no bacilli found. That the presence of the bacilli in the lumen of the intestine is closely associated with the appearance of the lesions in the intestinal wall, and in all probability to a great extent dependent upon these lesions, rather than that the lesions are dependent upon the bacilli and their products in the lumen, seems to be indicated and borne out by statistics. In other words it appears probable that the lesions forms the chief source of supply of bacilli to the intestinal contents, the injured and necrotic tissues acting as a favorable place for multiplication.

In considering this question of the bacilli in the intestinal contents, we must remember that as yet we are ignorant of the mode and even of the exact place of entrance of the organisms into the system proper, *i.e.,* into the fluids and tissues of the body, although some part of the digestive tract may probably without error be looked upon as the usual site of the invasion. At what point of the digestive tract and how the bacilli gain entrance to the tissues is not known, but it may be granted that it is not at the same place and in the same manner in all cases, and this may account for the intestine showing a greater reaction in some cases than in others.

Whether a proliferation of the organisms in the intestinal contents in ordinary cases takes place previous to the true invasion of the system has never been determined; it would, however, seem to be otherwise, since a fairly consistent result of investigations is the failure to isolate the organisms from the feces during the first week of the fever.

Experiments *in vitro* bearing upon the behavior of typhoid bacilli in the presence of colon bacilli would also seem to support this contention, but unfortunately these results are not to be absolutely depended upon and in any case have not as direct a bearing upon the subject as may at first be supposed. It must not be forgotten that the feces are by no means of a definite composition and reaction, and the products of the metabolism of the various organisms found in them must of necessity vary in kind, strength, and effect on account of the variety of food furnished them and its initial reaction—for instance it is conceivable that typhoid and colon organisms could live together and multiply provided the percentage of acid produced could be kept below a certain point. Even if the body is not capable itself of bringing about this condition, an organism producing alkali in quantity by its life processes might be present and thus counteract the effect of acid production by other organisms. My own experience and that of others indicates that the duration of life of typhoid bacilli in feces outside of the body is a very varying one, and even the power to multiply under these conditions cannot be denied, although it does not seem to be the rule.

However this may acutally be, and notwithstanding the possibility of such a primary increase of the organisms in the lumen, still it does not seem logical to suppose that a pre-invasion multiplication is usual, and that the organisms then practically disappear from the feces just at a time when the body resistance is overcome, and actual infection permitted. Either a steady increase from the time of ingestion it seems will have to be postulated, or the bacilli looked upon as being derived from the lesions of the intestine. The latter view is supported by present statistics. A reiteration of the alleged fact that typhoid bacilli may be isolated with ease from the intestinal contents during the first and second week of the fever and that thereafter these organisms are not supplied to the feces, or are entirely overshadowed by the presence and action of the supposedly more virulent colon bacilli, is found in writings on this subject, especially in England. A careful consideration of statistics at our command leads us to other conclusions.

To bring out more strongly the result of investigations on this point, the course of the disease may be divided into three arbitrary periods: First to tenth day inclusive; eleventh to twentieth day inclusive; and twenty-first day to convalescence. An analysis of my series of cases hows the following:

First to tenth day inclusive, number of cases examined, 28; typhoid bacilli isolated, 3; typhoid bacilli not isolated, 25; percentage of positive cases, 10.7 per cent.

Eleventh to twentieth day inclusive, number of cases examined, 44; typhoid bacilli isolated, 22; typhoid bacilli not isolated, 22; percentage of positive cases, 50 per cent.

Twenty-first day to convalescence, number of cases examined, 16; typhoid bacilli isolated, 13; typhoid bacilli not isolated, 3; percentage of positive cases, 81.2 per cent.*

Considering these cases more in detail, we find: Of twenty-eight cases examined previous to the eleventh day of the disease, only three were found to contain typhoid bacilli in the feces, *i.e.,* 10.7 per cent. The earliest of these isolations I find reckoned as on the sixth day, but the history was indefinite and the day was probably later; the next earliest as on the ninth, and one as on the tenth day.

In the second period, eleventh to twentieth day inclusive, forty-four cases were examined and typhoid bacilli isolated from twenty-two, *i.e.,* from 50 per cent.; three on the eleventh day, five on the twelfth, two on the thirteenth, four on the fourteenth, two on the fifteenth, two on the seventeenth, one on the nineteenth, and one on the

* Urine may possibly have contaminated some of these specimens, but allowing the maximum urine isolation, 25 per cent., we still have 50 per cent. to be credited to the feces.

twentieth. The larger number of positive results given on the eleventh, twelfth, and fourteenth days is due to the greater number of cases examined on these days. It is worthy of remark that four cases were examined on the tenth day, three being negative. Three on the eleventh day all positive, and five on the twelfth all positive. Two cases were examined on the thirteenth and typhoid bacilli were found; on the fourteenth five specimens gave the typhoid bacilli in four.

Sixteen cases were examined in the third period, twenty-first day to convalescence, and typhoid bacilli isolated from thirteen of them, *i.e.*, 81.2 per cent. Four of the positive findings occurred on the twenty-first day and the latest on the thirty-second.

Considering some of the foregoing cases individually, specimens from which were examined in the first and second periods, we find results consistent with the evidence given by grouping the outcome of examinations of feces from various cases. Thus:

Case XIX., bacilli present on sixth day, also on twelfth.

Case XXII., no bacilli present on tenth day; present on twelfth.

Case XXIII., no bacilli present on fourth, sixth, eighth, tenth; present on twelfth.

Case LXI., no bacilli present seventh and tenth; present twentieth and twenty-second.

Our technical methods being under good control, and giving positive results from other feces at the same time that the examinations of the above specimens were made, it is not likely that typhoid bacilli occurring in four consecutive specimens, such as those from Case XXIII., which were most carefully collected, could have escaped detection and isolation, even granting that they were present in especially small numbers.

These statistics seem to be borne out by those of other observers. Karlinski[29] could not detect the bacilli before the ninth day, and his twenty-one cases gave two on the ninth day, two on the tenth, two on the twelfth, nine on the fourteenth, two on the seventeenth, and three on the twenty-first.

Wiltschour[30] could not determine their presence before the tenth day, and Redtenbacher[31] in his review of statistics sums up by saying that in the majority of cases the bacilli first appear toward the end of the second week. Horton-Smith's[32] cases show the bacilli absent or not detected on the eighth, thirteenth, and ninth, while the same cases gave the bacilli on the eleventh, seventeenth, and fourteenth, when the second examination was made. Richardson[33] notes a positive result on the fifth day, but considers that the disease was probably further advanced. In fact the majority of envestigators do not even claim positive findings before the seventh or eight day, and the vast majority of isolations occur from the eleventh or twelfth day on. On the other hand, Rémy,[34] one of the latest workers on this subject, claims isolations as early as the third, fourth, fifth, sixth, ninth, tenth, etc., days, but declares, however, that it is difficult to determine the beginning of the disease, and that for ease of comparison he has always counted the day of the disease from the time when the patient took to bed. His positive results should therefore be reckoned as possibly occurring on days much later than the day indicated in his table. Rémy also attempted to estimate the number of colonies in plates to determine the relative proportion of the bacilli at various stages of the disease. His results seem to indicate that the bacilli, few in the early days of the disease, increase in numbers up to the second week (tenth day or later?) and then progressively diminish.

The conclusion which seems forced upon us by the results obtained in my own investigations and by those of others is that the bacilli do not occur in the feces, in numbers at least sufficient for recognition, much before the middle of the second week, or, in other words, about the time the intestinal lesions are well advanced and ulceration is occurring, and in the light of our present statistics on the subject (which may of course be modified by subsequent research) it seems most rational to look upon the presence of the organisms in the feces, especially in fair numbers, as indicating an ulcerating condition of the intestine, and that the organisms practically appear and disappear with these lesions—few when the lesions commence to break down, they increase as this process advances and commence to decrease as the ulcers begin to granulate and heal.

It must unhestitating be admitted, as noted previously, that there may be a period immediately following the ingestion of the bacilli during which it might be possible to isolate the organism from the intestinal contents, and it must not be overlooked that any condition giving rise to a serous discharge into the lumen might possibly bring about the presence of the organisms there before ulceration, even if infection had not had its immediate seat in the intestine; still as far as we have been able to determine, the organisms are absent during the early days of the disease, and do not appear in force until the time of severe intestinal involvement and ulceration.

Another hypothesis which may be offered in solution of this problem is that the organisms are continuously present in the lumen of the intestine from the day of ingestion, but, while overcoming the natural resistance of the body and while adapting themselves to a new environment, are unable to actually increase their numbers to any great extent, and are hence in such small force as to be detected with great infrequency. As the adaptation of the bacilli to their environment becomes more perfect and the resistance of the invaded organism is gradually overcome, conditions adverse to the bacilli are for a time overborne and they steadily increase and may then be detected with less and less difficulty. Although such may be the case, and undoubtedly these factors are to be reckoned with, this hypothesis, at present, does not seem to coincide with all the facts, such for instance as that of the apparent

continued absence of the bacilli from the stools of cases of the fever, which give all other clinical symptoms and tests, and which would probably be found to have little or no intestinal involvement or slight or few ulcers.

The gall-bladder, as is known, may contain the bacilli at some period of the disease, and must not be forgotten as a possible source of supply of the organisms to the intestinal contents. The bacilli from this source would, probably, under ordinary circumstances, appear not earlier than the second week, and whether they would survive to be discharged from the body has certainly as yet not been determined.

To what extent the presence and multiplication of the bacilli in the gall-bladder may affect the intestinal flora, we have no ready means of determining, and the problem must be solved by careful observation and analysis of intestinal and gall-bladder contents of cases dying without intestinal lesions or after the healing of these lesions. What these examinations will show cannot be foretold, but nevertheless it may be taken as generally true that the organisms of the disease tend to appear in the feces at a time corresponding to the breaking-down of the intestinal lesions, and to disappear gradually as those lesions granulate and heal, and finally generally vanish before the temperature reaches normal. We probably therefore have a fair index to the state of the intestine at any given time or in any given case in the occurrence and number of typhoid bacilli in the feces, although this may to some extent be influenced by the struggle going on among the intestinal organisms, or in the later stages by bacilli derived from the gall-bladder.

If we have interpreted our statistics correctly, as to the usual source of supply of typhoid bacilli to the feces, then the organisms must be present in the hyperplastic intestinal lesions, *i.e.*, the tumefied agminated and single follicles, and it is from these, at least during the height of the disease, that the bacilli are largely supplied to the intestinal contents, and I venture to conjecture that a marked tumefaction and ulceration of these structures in man do not occur unless the bacilli are present in them, that is, that they are not to any great extent dependent upon toxins, carried to these parts from a distance in the system, or absorbed from the intestinal lumen. This I am aware does not agree with some of the present conceptions of typhoid fever, which conceptions may be principally attributed to unsatisfactory technic and the results of animal experiments such as those reported by Sanarelli, who asserted that the presence of the bacilli of Eberth was in no wise necessary to the very characteristic and complex phenomena which develop in the intestine, and that the bacilli can act from afar in virtue of their poisons, while they themselves remain localized by preference in the serous membranes, as among the animals, or in the spleen, as in man. This may be perfectly true when lethal doses of the bacilli or their toxins are administered to animals, but we cannot argue from this that it is necessarily true of the infection as it occurs in man, in whose case the primary dose of poison or bacilli is probably never very large, and the general poisoning often slight, the disease unfolding itself slowly.

It is well known that certain cells and tissues show a peculiar susceptibility to the action of certain poisons, while other cells and tissues remain unaffected or less affected in the presence of the same poisons. It is also true that the anatomical position of various cells, especially their proximity to the blood and lymph streams, renders them more liable to injury than cells not so situated when poisonous substances are present in the circulating fluids. Other cells, there is little doubt, may be especially exposed to toxic influnces because they themselves, or the tissues of which they form part have some particuar function of secretion, elimination or absorption. From these premises it may be logically argued that not only the less characteristic degenerations and lesions of a disease, but even focal and more pathognomonic lesions may be brought about by the simple presence of bacterial products in the fluids of the body. Experimentation has shown this in some instances to be the case. It does not necesssarily follow, however, that all the lesions which characterize a given infection can be brought about by the simple introduction or absorption of the toxins of the disease. In an infection such as typhoid fever, it is probable that the localization of the bacilli is necessary to the development of certain lesions; that besides the products, which by their presence in the blood and lymph streams give rise to some of the lesions, there are other substances only present or sufficiently concentrated in the immediate vicinity of the bacilli, which give rise to other lesions characteristic of the disease.

Because the morphological examinations of tissue sections, to determine the relation of the bacilli to the lesions of typhoid fever, have in most instances proved unsatisfactory, and have given inconstant results, it has been too readily concluded that any or all the lesions can be developed completely independent of the immediate presence of the bacilli. Our present knowledge hardly warrants such a conclusion, and it may be well to keep in mind that it is from the tissues in which the principal lesions occur that the bacilli can be isolated with great regularity.

The intestinal tract being the usual portal of entry, the lymphatic tissue of the intestine is without doubt often the earliest seat of the organism within the tissues, and the peculiar and characteristic lesions induced in it are probably dependent upon the immediate presence of the bacilli and certain products thereby concentrated. These products, it has been shown, not only give rise to degeneration, but may incite the endothelial cells to reproduction or act chemotactically and attract the cells of the system which aggregate and lead to the tumefaction which may eventually result in necrosis and the formation of ulcers.

After invasion of the tissues, wherever the point of entry may be, the bacilli probably commence operations in the least resistant lymphatic tissue to which they may be borne, and there in the course of growth and death give rise to their various poisons, and gradually spread to fresh regions through the agency of the blood and lymph, and especially so as the primary systemic resistance is overcome. If for some unusual reason the tissues of the intestine are particularly resistant, the lesions induced in them may be slight, or, if we can depend upon the cases reported, entirely absent. This absence of lesions may, on the other hand, indicate that the bacilli have gained entrance to the system by a channel other than that usually suspected, and the bacilli not have reached the intestinal structures.

The appearance of the bacilli in the spleen, bone marrow, mesenteric glands, blood, rose-spots, and urine, is dependent upon the secondary dissemination of the bacilli by the blood and lymph channels. The blood seems to be a very unfavorable medium for the organisms, and to exert a strong germicidal action on those bacilli which are not rapidly carried to a more favorable place of abode. The continued presence of the bacilli in the spleen is probably to a great extent dependent upon the large quantity of blood passing through this organ and the deposit there of the organisms borne by it. We do not know whether the spleen is a particularly favorable place for the organisms and usually acts as a focus of multiplication or not. The immediate presence of the bacilli and their probable degeneration in the spleen possibly indicates the principal cause of the characteristic enlargement of this organ.

The recent work of Neufeld[35] on the isolation of the bacilli from the rose-spots, and especially that of Fraenkel[36] on the demonstration by special technic of the organisms in excised spots, indicate not only that the bacilli are spread throughout the system by the blood, but that these lesions are also dependent upon the immediate presence and probably upon the degeneration of the bacilli and are hyperplastic in character. The bone-marrow reactions are possibly of the same character and due to the same causes. This would also seem to support the contention that besides the greater abundance at the points of localization of the bacilli of the diffusible poisons which give rise to the more general inflammations and cell degenerations, especially parenchymatous, throughout the system, there are less soluble products, probably derived from the disintegrating bodies of the bacilli, in all tissues where the bacilli find a place of lodgment or safe abode and multiplication, and that at these points true hyperplastic lesions or chemotactic phenomena are induced, which lead to the characteristic tumefactions and at certain points, as in the intestine, to the subsequent degenerations and ulcerations which are almost pathognomonic of the disease. The association of the bacilli with post-typhoid suppurations lends support to this view.

The fact that the urine frequently contains the bacilli is good indirect evidence of the presence of the bacilli in the blood at some period of the disease. This is the most likely channel by which they reach the kidneys, and through the kidneys in various ways they pass into the urine from the circulation. Conditions giving rise to transient toxic inflammations and to albuminuria may bring about changes favorable for the passage of the bacilli, or in some instances the severer focal lesions which have been described in the kidneys, and which are undoubtedly due to the localization of the bacilli may be the forerunners of the appearance of these organisms in the urine.

Before turning to the hygienic aspect of our subject let us sum up briefly the present status of the bacteriology of typhoid fever, and in so doing call especial attention to those points in the history of the bacilli within the body upon which we are particularly ignorant.

In the first place we do not know the mode or exact portals of entry of the bacilli into the tissues and fluids of the body. The usual site of invasion is, however, in all probability in the lower portion of the small intestine, where involvement most frequently occurs. Some other portion of the gastro-intestinal tract may at times be the site of the primary localization, and the lungs as portals of entry cannot with certainty be ruled out. We do not know whether, after the ingestion of the bacilli, they steadily increase in the lumen of the intestine, there producing their toxins, and by these causing intestinal disturbances and inflammations, and by their absorption systemic symptoms; or whether, when in the lumen, they are unable to increase, but gain entrance in some manner into the lymphatic tissues, and there by toxin production and multiplication give rise to typical infection and lesions.

We do know, however, that it is certainly not usual to be able to isolate typhoid bacilli from the intestinal contents during the first week of the disease, but that this can be done with much regularity toward the middle of the second week. These results point to the lesions and symptoms as being principally due to the invasion of the tissues by the bacilli.

We know, also, that the organisms can be isolated from the rose-spots, which ordinarily appear during the second week; and that they can be isolated from the spleen, and this probably quite as early as the appearance of the rose-spots; and also that they frequently appear in the urine at the end of the second week, and are generally associated with albuminuria.

And, finally, we have seen that they can be isolated from the circulating blood, which fact indicates the most likely channel by which they have reached the spleen, rose-spots, and urine.

After death, the bacilli have been found in connection with lesions in various locations, especially in the mesenteric glands, liver, and bone marrow. The first indicating a direct spread by the lymphatics, and the probable passage of the organisms into the general circulation by the

thoracic duct; the lesions in the liver, a spreading by the portal circulation, and the bone-marrow, like the spleen, rose-spots, and kidneys, again indicating their dissemination during life by means of the general circulation.

Notwithstanding, then, the gaps in our knowledge, we are now in a position to say definitely that no matter what the actual condition is during the first week of the fever—whether the chief symptoms are due to toxin absorption from the intestinal contents, or, as seems more likely, are due to a true infection well established at that time, that by the second week a true tissue infection is established, and the bacilli are scattered, living, and probably multiplying in various situations in the body, which situations they have reached through the agency of the lymphatic and blood streams.

The blood, as has been stated, does not seem to be a favorable fluid for the life of the bacilli, and only in the rarest instances is it at all likely that they multiply in it, but some simply survive long enough in it to reach more favorable places of abode.

Typhoid fever, then, although it cannot be looked upon as a true septicemia, holds an intermediate place between the purer intoxications such as diphtheria, cholera, and tetanus, and those truer types of blood infection in which a growth and multiplication of the infecting bacteria take place in the blood, and which more truly deserve the name of septicemia or bacteriemia.

Hygienic Considerations.

During the past few years bacteriology has contributed much to our knowledge of the occurrence of typhoid bacilli in the excretions and secretions of typhoid-fever patients, and a due appreciation of these results should give a sound foundation for hygienic procedures for the limitation of this too prevalent disease.

Mouth and throat secretions and exudations may be carriers of the specific organisms, which fact warns us of the extreme care that should be exercised in regard to sterilization and disinfection of all utensils used by the patient for eating or the taking of medicine, as well as the destruction of all food in contact with which such eating utensils have come. It is no uncommon occurrence for food, especially dainties, to be shared by patients and the family, the patient in many cases having first eaten from the dish which is subsequently passed around.

The feces, being very generally considered the carriers of the organisms, have been disinfected with some regularity where the diagnosis of typhoid fever has been made. Fortunately, as far as we know, the organisms do not appear in the stools, at least in great numbers, before the patients have taken to their beds, and in most cases have, as far as we can determine, entirely disappeared at the setting in of convalescence. The stools, then, are a source of infection generally during a period when their disinfection can be easily accomplished and only ignorance or carelessness on the part of the attendants is likely to cause the deposit of a non-disinfected evacuation where it may become a menace to the community at large.

Such a statement cannot be made in regard to the urine. Here, the organisms, as in the feces, are generally absent in the early stage of the disease, but may appear later, or even during convalescence, and persist in the urine indefinitely, and often in astonishing numbers. It is not, at least, the general practice to make a special point of disinfecting the urine, even during the febrile period, or to determine the presence or absence of the typhoid bacilli in the urine of patients convalescent or sufficiently recoveryed to be discharged from hospitals, or in private practice ordered away to recuperate. Such invalids only too frequently resort to some outlying district where the lack of modern sanitary arrangements permits the ready contamination of the water supply and the establishment of a new focus for the dissemination of typhoid fever. Further, the great danger from the unavoidable soiling of the clothes in such cases is too apparent almost to be mentioned, and the infecting of the hands is certainly of frequent occurrence.

The danger from infection by means of the urine is to be strongly emphasized, and undoubtedly many lives and days of illness might be saved if this fact were more generally realized and acted upon.

No patient should be discharged from a hospital before an examination of the urine for the infecting organisms has been made, and, if these are present, an attempt made to eliminate them; or at least the patient warned of his condition and instructed in the care of himself and his fellows. In all cases, in fact, both in hospital work and in private practice the routine disinfection of the urine should be instituted, and before its discontinuance the urine should be determined free from the bacilli of typhoid. Certain facts and procedures may be considered in this connection.

Albumin furnishes food material for the bacilli, if it is present in the urine, and when the organisms gain access to the bladder they often increase enormously; conditions giving rise to albuminuria are probably also conducive to the passage of the organisms from the system through the kidneys to the urine, hence cases showing albumin are especially liable to contain the bacilli; cases in which albumin is absent cannot be considered as always free from organisms, but my experience has been that the bacilli do not tend to linger in such urines.

In districts remote from laboratories, a hanging drop or stained cover-glass preparation of fresh centrifugalized urine might be examined; if rod-shaped organisms are present, these should be looked upon as typhoid bacilli and the urine as infectious until their disappearance. Where possible, a definite diagnosis by means of culture tests should be made. Certainly this problem should be considered very seriously and

is scarcely less important than that of diphtheria, in the case of which routine bacterial exterminations have been established and the freedom of patients restricted. Every precaution should be taken to eliminate the possibility of immediate infection from such cases, as well as the dissemination of the specific organism in communities less well protected sanitarily than our own, and which constantly supply us with many of our cases of typhoid. It is probably only through such precautions that the prevailing death-rate from typhoid fever will be greatly lowered, since we cannot hope to enforce universal purification of water, which we wilfully or ignorantly allow to be contaminated.

General Conclusions.

1. During the course of typhoid fever, usually after the first week, typhoid bacilli can frequently be obtained from the blood, spleen, rose-spots, urine, and feces, and in rarer instances, it is claimed, from the secretions or exudations of the mouth, throat, and lungs. After death the bacilli have been demonstrated in these and other locations and lesions, such as the lymphatic tissues of the intestine, the mesenteric glands, bone-marrow, lungs, liver, gall-bladder, kidneys, etc.

2. The bacilli, as far as can be determined from various observations, do not thrive or even survive long in the circulating blood. They are, however, able to live and multiply at some, at least, of the points at which they are deposited by the blood and lymph, thus forming bacterial foci within the tissues.

3. Morphological examinations of tissue sections to determine the relation of the bacilli to the lesions of typhoid fever have in most instances proved unsatisfactory and have given inconstant results. Some of the lesions, without doubt, occur at points remote from the bacilli. On the other hand, it is probable that the bacilli are intimately associated with many of the lesions, since wherever the bacilli, after gaining access to the tissues and fluids of the body, find lodgment and establish foci, after gaining access to the tissues and fluids of the body, the various products of bacterial metabolism and degeneration are thus concentrated and doubtless give rise to lesions at these points. Moreover, it is not unlikely that certain lesions occur only at points of localization of the bacilli.

4. Typhoid fever, therefore, is an infectious disease, in which a wide dissemination and multiple localizations of the bacilli are frequently demonstrable both during life and after death. During the course of the disease, various tissue changes take place, some necrotic, others hyperplastic. Some of these lesions are at points remote from the inciting organisms; certain facts, however, point strongly to a close association of the bacilli with some of the more characteristic lesions, especially those of the lymphatic tissues.

5. There is a close connection, in time at least, between the appearance in, and disappearance from the intestinal contents, of the typhoid bacilli and the appearance and repair of the intestinal ulcers. The organisms are only very rarely demonstrable in the stools before the first days of the second week and disappear with the fall of the fever. During the period at which intestinal tissue destruction is most active they can be isolated with great regularity. When continuously absent in typical cases, this may be looked upon as indicating a probable scarcity or absence of intestinal lesions.

6. The urine in a certain percentage of cases contains the bacilli, though not often before the end of the second week. The organisms may not appear until very late in the disease or during convalescence. They may persist for days, weeks, and it has been claimed for months, and are generally associated with albuminuria.

Hygienic Conclusions.

1. The urine of typhoid fever patients should always be disinfected. From a hygienic standpoint bacteriological examination of the urine of patients convalescing from typhoid fever is important and should never be omitted before patients are allowed to go at large, so that proper precautions may be taken to guard against the dissemination of typhoid bacilli by the urine. This is an often neglected source of infection that should be seriously considered in the hygiene of typhoid fever.

2. Feces, of course, should be disinfected at all stages of the disease, but the organisms being present generally only from the beginning of the second week to the fall of the fever and the patient during this period usually being confined to bed, the feces are not such a source of infection to the community at large as the urine.

3. The bacilli may on account of the lung and throat lesions be present in the mouth of those suffering from typhoid fever, hence the expectoration should be disinfected, as well as all eating utensils, etc., used by the patients.

RESTORATION OF USEFUL VISION IN A COMPLICATED CASE OF ACUTE INFLAMMATORY GLAUCOMA OF TEN DAYS' DURATION WITH VISUAL ACUITY REDUCED TO THE PERCEPTION OF LIGHT.[1]

BY C. A. VEASEY, M.D.,
OF PHILADELPHIA.

On the third day of April, 1897, I was asked to see in consultation R. T., an unmarried woman aged forty-two years, who was suffering from a very severe attack of inflammation of the eyes of nine days' duration. The attack, which had been preceded by transient paroxysms of foggy vision lasting for an hour or two, as well as by a halo of colors around artificial lights, was typical of acute inflammatory glaucoma coming on during the night and for the first twenty-four hours producing intense pain. After this time, however, during the whole course of the disease, the pain was scarcely noticeable. Beyond the employment of a boric and zinc lotion nothing had been done for the condition which at the time of my first examination was as follows:

The right eye was intensely injected, the cornea hazy and anesthetic, the anterior chamber shallow, the aqueous turbid, the pupil widely dilated and immobile and the lens quite hazy. No view of the fundus could be obtained. Tension equaled + 3 and vision equaled the perception of light, and according to the statement of the patient the latter had been so since the onset of the attack. The light field was considerably contracted on the nasal side.

In the left eye similar conditions were present with the addition of a yellowish degenerated iris and a cataractous lens. The vision was totally abolished.

The history elicited at the time of this examination showed that a similar attack had occurred six years before, but affecting the left eye only, and that in spite of continued medicinal treatment by an oculist the vision was ultimately lost.

With one eye blind and the other possessing only light perception, in a patient with an attack of acute inflammatory glaucoma of nine days' duration, it was realized that no time was to be lost if any vision was to be restored. Leeches, hot fomentations and repeated instillations of eserine not having made any impression upon the eye by the following day, an upward iridectomy was performed under ether anesthesia, the anterior chamber being so shallow that a Graefe knife was employed instead of a keratome. Beyond a smart hemorrhage at the time of cutting the iris, no complication was encountered. The tension was at once restored to normal, the anterior chamber quickly reformed, the eye became much more quiet, the visual field became larger, persons moving around the room were detected and recognized, but it was noted that the lens was quite opaque and considerably swollen.

The condition continued *in statu quo* for two months, the patient being able to count fingers at one meter, when she came to see me one day with the eye even more markedly inflamed than when I first saw her. The lens was enormously swollen, the anterior chamber shallow, the iris inflamed and attached to the anterior capsule, tension equaled + 2 and vision was again reduced to the perception of light.

The conditions, therefore, were now those of a secondary glaucoma brought about by the swelling of the lens and the accompanying iritis, and the only chance to restore any of the vision seemed to be in the immediate removal of the lens matter. Under ether anesthesia, through a three-millimeter flap made in the sclera instead of in the limbus so that the advantages of a sclerotomy might be obtained, most of the lens substance was extracted. The upper portion of the capsule was so tough that it had to be removed with forceps. Notwithstanding the severe inflammatory conditions that were present at the time of the operation, the healing was not unusually prolonged and at the end of a month the patient was tested for glasses and was found to possess $^{5}/_{40}$ vision.

She was now seen once a month for six months, the eye continuing well and quiet when she passed from observation to reappear a year later with the pupil almost entirely closed and the eye presenting the appearance that one sees after chronic iridocyclitis following cataract extraction. She admitted having had two or three attacks of inflammation in the eye in the interim, but had thought nothing of them as they did not seem to disturb her vision very much. Now that the latter was distinctly bad again she had come for advice. The eye was absolutely quiet and vision equaled the counting of fingers at twelve inches.

A small iridocystectomy was now made down and out, the iris being withdrawn with some difficulty with a blunt hook. An opening about 2½ millimeters in diameter was obtained which, after the healing was complete, with the correcting glass enabled the patient to have a visual acuity of $^{5}/_{60}$. The pupil remained open and the vision continued as long as the patient was under observation, which was six months from the time of the performance of the operation; but as to the exact present condition the writer is unable to state from personal observation though he has been indirectly informed that the visual acuity is still maintained and that there have been no further inflammatory attacks.

The case seems to the writer to possess several points of interest the chief of which is the restoration of vision after it had been lost for

[1] Read before the Section on Ophthalmology of the College of Physicians of Philadelphia, December 18, 1900.

ten days and notwithstanding the fact that it was necessary to perform the second operation during the height of a severe inflammatory attack involving the anterior portion of the uvea.

RUPTURE OF THE RIGHT KIDNEY: NEPHRECTOMY: RECOVERY.

BY G. R. TROWBRIDGE, A.M., M.D.,
OF BUFFALO, N. Y.;
ATTENDING SURGEON TO FITCH HOSPITAL; SURGEON TO LEHIGH VALLEY R. R. CO

Rupture of the kidney being a comparatively rare occurrence, I report the following case on this account, and because of the apparently hopeless prognosis and the surprisingly excellent result. All authorities agree that this accident to a kidney is serious and one which demands rapid interference.

The cause of ruptured kidney is external violence applied over the region of the organ, usually when the individual is in a stooping posture. The position, I believe, has a very great deal of influence on the result of a blow in this locality, for when a person is stooping all structures both superficial and deep, are put upon the stretch, offering less resistance and protection to the underlying kidney than does the erect position.

The signs and symptoms are agreed upon by all authorities, and in the main are as follows. A history of violence over the organ; hemorrhage *per* urethra; a sense of fulness about the kidney, often discoverable by palpation; pain extending into the groin and testicle of the same side; weak pulse; pallor of mucous surfaces and the skin, and signs of collapse. All these signs vary with the extent of the injury, although I do not think signs and symptoms should always be taken as an indication of the extent of the rupture. The hemorrhage may be severe, the blood clotting in the bladder and blocking the urethra, or it may be so slow, that in the absence of an exploratory operation the surgeon is misled, and sepsis and peritonitis result from a too-long-delayed operation.

The hemorrhage from the urethra might be confounded with that from an injured mucous surface of the bladder, but, taken with other signs and symptoms, should not be difficult of differentiation. Often the hemorrhage might be severe and still not show externally, due to the clot formation in the bladder, and this condition itself might necessitate a cystotomy for its relief.

W. W. Keen[1] reports five cases of primary nephrectomy with one death, a mortality of 20 per cent., and thirteen cases of secondary nephrectomy with five deaths, a mortality of 38.5 per cent., showing the primary operation to be the preferable one of the two. As to route, he recommends the lumbar operation.

Ernest Laplace[2] makes the following statement: "The dangers of rupture of the kidney are mainly hemorrhage and sepsis. When, therefore, the symptoms are such as to indicate marked hemorrhage or sepsis, and especially if a tumor form quickly in the lumbar region, an exploratory operation should at once be done. If severe laceration be present or the kidney's functions be practically compromised, or the hemorrhage be such as to require ligation of the renal vessels, lumbar nephrectomy should immediately be performed, primary nephrectomy being safer than secondary removal of the organ."

On the other hand, Tuffier[3] reports five cases of traumatism of the kidney, all recovering, operation in one case only. He believes that operative interference should be exceptional and only resorted to when there is hematuria.

In answer to this I can only reiterate my statement that a severe hemorrhage may occur without being visible, and therefore the hematuria cannot be taken in all cases as a reliable sign, either for or against the extent of injury.

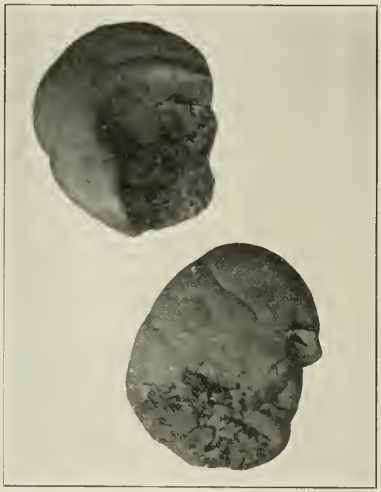

Fig. 1. Ruptured Right Kidney.

Henry Morris[4] says: "There is great danger in delaying operation in these cases, the decomposition of the clots and the cystitis which is excited by their presence, as well as the frequent catheterization needed, expose the patient to all the dangers of suppuration of the wounded kidney and also to the risk of infection.

The following case, I think, presents the prominent signs and symptoms of severe trauma of the kidney and shows what may be accomplished by an immediate nephrectomy.

Michael S., Pole, aged forty-three years, weight 150 to 160 pounds, height, 5 feet 8 inches; laborer. On April 24, 1900, was struck by a coal-car going rapidly down a grade in the tunnel of the coal-trestle of the Lehigh Valley R. R. This tunnel is cut through solid lime-

stone and the walls are consequently unresisting. Whether he was struck in the back by the car itself and thrown against the side of the tunnel, or whether he struck his back against the wall of rock, I was unable to ascertain and he was not positive about it himself. He was brought five miles to Buffalo on a locomotive and taken to the Fitch Hospital. Immediately on his admission he expressed a desire to urinate and passed nearly one and a half pints of bloody urine. This was before I reached the hospital. After my arrival (about twenty minutes after his admission) he passed an amount of bright arterial blood equal to three pints. Pulse was weak and very rapid. Patient complained of soreness and fulness over right kidney, the latter being evident by palpation. The mucous surfaces and also the entire skin were pale and anemic. Intravenous injections of normal salt solution and hypodermic stimulation were at once employed, together with hot-air baths. As it was the first case of the

Fig. 2. The Resultant Scar.

kind I had ever seen I called in Dr. E. J. Meyer of the hospital staff to verify my diagnosis. This he did and immediate operation was decided upon.

The man was quickly prepared and a lumbar nephrectomy performed. The hemorrhage was very severe and for a few moments the result looked extremely doubtful. Normal salt solution and hypodermics were again resorted to, with good results. I found the kidney torn about three quarters through and in its removal the rupture was completed, the organ being removed in two pieces. Several ligatures were applied to the vessels, the wound cleansed and closed throughout two-thirds of its extent, the remaining third being packed with iodoform gauze.

The left kidney assumed its double duty without trouble and the patient made an uninterrupted recovery. The after-treatment consisted of sweating, injections of normal salt solution and hypodermic stimulation, together with considerable quantities of drinking water. At the present time the man is again doing his work as formerly and is in perfect physical condition.

The kidney was somewhat larger than normal and quite friable.

The accompanying illustrations give a good idea of the extent of the damage and the resultant scar.

The conclusion I draw from my experience in this case is this: In cases of trauma of the kidney, do an exploratory operation, for by this means alone is it possible to learn the extent of the injury.

For the photographs in this case I am indebted to Mr. N. B. Ludlum, Assistant to Superintendent Van Allen of the Lehigh Valley R. R. Co.

MEDICAL PROGRESS.

Radical Cure of Abdominal Hernia.—Dr. Salistscheff (*Centralbl. f. Chir.*, No. 13, 1901) states that he has succeeded in making actively contractile firmly united muscle-flaps for the closing of old abdominal hernia at the site of operations or wounds. In one of his described cases an obstinate hernia followed a wide stab wound through the left rectus abdominis in its upper half. Freely opening the sheath of the muscle above and below the locus of the hernia and thus exposing the cut ends of the muscle, he constructed an upper and a lower rectangular muscle-flap respectively out of the upper and lower stumps of the divided muscle. These he turned up and down, approximating their cut edges over the exit of the hernia, closed by the usual methods and there sutured them. Primary union and subsequent observation of the case showed that the result was most satisfactory. In another patient the hernia was in the right inguinal region along the border of the right rectus. In this case the muscle-flap was cut from the rectus so that it could be swung on the pubic attachment at a point outward across the hernial opening, where it was sutured to the freshened edges of the latter. This flap also lived to be contractile and fully adequate for curing the rupture. The other steps in these operations were the same as for closing any hernia wound. His patients have been under observation for many months and the results seem to be permanent.

Medical Hebetude.—An absolute lack of surgical-obstetrical sense is clearly shown to the startled reader in J. McElroy's recent report of a case (*British Med. Jour.*, Apr. 6, 1901). Mrs. F., aged thirty-seven, multipara, six months pregnant, had felt no movement for three weeks. In examination the child was pronounced *dead*.

Two days later she was comatose; stertorous breathing, frothing at the mouth, pupils dilated and fixed. Urine loaded with albumin. Jalap, bromide and chloral ordered. Frequent convulsions. Calomel, jalap and ginger prescribed. Violent delirium. *Seven* days from the onset of this eclampsia a "macerated" fetus was passed!

Does Typhoid Immunize?—In a series of reports of cases from the Cape and from India, of soldiers and orderlies of whom he had very complete histories, B. Nicol (*Lancet*, Apr. 6, 1901) gives his reasons for believing that such immunity does not exist. In these cases a second attack occurred within a few months of the first, and in some instances, a third. In all, Widal's test was distinctly present but a short time prior to the secondary attack. This seems to him to cast a doubt on the value of the test for determining the presence of immunizing substances in the blood. That immunity exists, he has no doubt; it is not, however, brought to light by Widal's test, nor is it the result of a previous attack. It is a purely individual characteristic which unfortunately for those who might otherwise be guarded from infection, there is as yet no means of determining.

Skiagraphy and Calculi.—C. L. Leonard (*Annals of Surgery*, April, 1901) after an analysis of the results of skiagraphic examination of 136 cases of actual and suspected cases of renal calculi and the discovery among them of seventeen renal and nineteen ureteral stones, draws the following conclusions: (1) Skiagraphy furnishes accurate and valuable negative and positive diagnosis; (2) ureteral calculi are more common than has been supposed, perhaps as much as 50 per cent. of all cases; (3) equally accurate diagnosis of calculi is impossible by all the other means; (4) this method is comprehensive, aids operative intervention by locating the calculi and by excluding the opposite kidney; (5) non-operative treatment in the absence of a negative X-ray diagnosis is irrational and dangerous in all suspicious cases; (6) this method has precision and mechanical exactness in its favor, but, in order to avoid error, accuracy in technic and care in interpreting results are needed; (7) the diagnosis by this method of small calculi low down in the ureters, which may be expected to pass, make a non-operative treatment rational; (8) negative diagnosis does not preclude exploratory nephrotomy, but does render unnecessary actual incision into the kidney in search for calculi; (9) dilatation of the ureters in the male may be practised with the aid of a suprapubic cystotomy for guiding the sounds from the urethra to the ureter. It will be as serviceable in the male as in female, without the cystotomy.

Gastric Insufflation.—R. Oehler (*Semaine Médicale*, No. 12, 1901) states that although percussion of the stomach unaided is a valuable diagnostic means, it is very uncertain unless combined with a distention of that viscus with air, either through the medium of some effervescent mixture internally administered, or of the stomach-tube through which air is pumped at once into the organ, or of a large tube passed partly down the esophagus and used the same as the gastric siphon. All these procedures have objections for the practitioner and patient alike. A simple, rapid means of insufflating the stomach he has found to be the Pollitzer bag. The patient is placed in the dorsal decubitus position and the tip of the bag is passed into one nostril while the other is occluded. While the patient swallows water he is compelled by the bag to swallow air also. A few repetitions of the act are enough to dilate the stomach in most individuals.

THERAPEUTIC HINTS.

Hemoptysis.—If the bleeding is moderate in amount, Lemoine (*Le Nord Médicale*, Apr. 1, 1901) advises a hot foot-bath, and purgation with:

℞ Sennæ)
Sod. sulphat., (aa.....gm. 15.0 (℥ss)
Aq. bullient. ad.....c.c. 500.0 (Oi)

Or if the bleeding is subsiding use simply magnesium sulphate. For continuous small bleedings a good prescription is:

Quinine sulphat....gm. 0.30 (gr. v)
Ergot pulv..... 0.50 (gr. viij)

in capsule, every morning. In sudden large hemorrhages, omit the foot-bath and envelop the legs in iodized cotton and bathe the hands in hot water to open up the peripheral vessels. Perchloride of iron is useless, and ergot not very good, but ergotole may be given hypodermically. Perfect rest, control of cough, and avoidance of food are necessary for a time.

Melancholia.—M. Allen Starr believes it better to keep a melancholic asleep than to attempt to relieve his distress by diversion or anything which demands a mental effort which he cannot make. Severe cases require absolute quiet and rest in bed, and precautions should be taken against sudden impulses to suicide. The treatment of light cases without delusions consists in increasing nutrition by frequent feeding, milk punches, tonics, stimulants, laxatives, and aids to digestion, and the forcing of fluids, especially milk and beef extracts. Glycerophosphates, intestinal antiseptics, warm baths, alternating hot and cold douches, massage, out-of-door exercises without fatigue, vasodilators and cardiac stimulants, all have their value. Insomnia must be combated by hypnotics, which must be changed from night to night. Opium is constipating and should be used only when there is distress, but it does not cause the habit and is specific in relieving the mental symptoms. Quiet may be obtained in a country place or sanitarium, not in a city.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 Fifth Avenue, New York.

SATURDAY, MAY 11, 1901.

NEW YORK'S OPPORTUNITY.

As the far away rumbles of thunder are but precursors of a coming storm so the periodic signs of discontent regarding the care and treatment of the insane as now attempted, should presage some radical departures in the near future.

The taxpayer is unquestionably paying too much money for the results obtained in the care and treatment of its insane, and New York State, as a thrifty community, should heed the advice recently put forth in the Report of the State Charities Aid Association to the State Commissioners in Lunacy.

It takes up one phase of the problem, already dwelt upon in the Medical News in December last and more recently in a paper on "Charity and at Less Cost," that is, that more money could be spent on the acute insane and less on those incapable of being helped.

This report says: "Insanity is not necessarily a disease confined to the brain, as is commonly supposed. The brain and the central nervous system are so intimately connected with every tissue and organ in the body that disease or disorders outside of the nervous system may be causes of insanity. Thus, mental symptoms may result from the defective assimilation of food, from impaired circulation, from malnutrition and from numberless other morbid conditions. In the nature of the case, these causes are as obscure as they are numerous. To isolate them, to recognize them, to determine their mode of action, is the most important object in the study of mental diseases to-day. For experience has shown that treatment directed toward causes is the only rational method of combating disease. The investigations which such work implies can only be carried on by the most industrious and skilful workers, and should be conducted by the ablest of our alienists and neurologists.

"Why should not the insane have the benefit of the best medical skill our country affords, and which is now so freely given gratuitously by the most distinguished members of the profession to patients suffering from other diseases in other hospitals of every city of this State?

"The plan we would advocate is the erection, in several of our largest cities, of comparatively small Reception Hospitals, or Psychopathic Hospitals, as branches of existing State Hospitals and governed by the same boards of managers. These hospitals, designed for the reception and temporary treatment of insane patients, should be organized on the same general plan as are the New York, Presbyterian, St. Luke's, St. Vincent's, Roosevelt, and Mount Sinai Hospitals of this city, and other well managed hospitals elsewhere. Cases possibly curable would doubtless be kept for a limited period in the reception hospital under the daily care and constant advice of the most eminent members of the profession, until it was thought best to send them on to the main hospital.

"It is also desirable that the reception hospital should open its doors for clinical teaching. It is in the cities that are centered the medical schools which send out year after year graduates who know but little of mental diseases, because they have not had the proper facilities for studying them. Many of these young doctors begin their practice with very slight knowledge of a group of diseases which they will inevitably during their professional career be called upon to treat. It is also under the roof of the New York Reception or Psychological Hospital that the already established Pathological Institute would naturally find its home."

As for the chronic insane they should be sent to the country where agricultural colonies could

be formed which under efficient, non-political management, could be made almost, if not quite, self-supporting.

Small psychopathic hospitals in large cities for the acute and curable insane, and large agricultural colonies in the country for the chronic insane is the answer to one phase of the question. How best to take care of our insane?

THE AMBULANCE SURGEON AND YELLOW JOURNALISM.

The average newspaper writer never succeeds so well in producing a comedy as when he attempts a tragedy, and the sublime height of journalistic comedy is reached in reports of medical affairs. A good story bears telling twice and an element of fiction merely increases its interest. The ambulance surgeon furnishes the foundation in many cases and upon some simple occurrence the yellow journals erect a melodrama. And every month or two they repeat the tale.

Their latest fabrication concerned the death from cerebral hemorrhage of a woman at the New York Hospital, after what was claimed to be an incompetent and insulting diagnosis of the ambulance surgeon who left the patient, but was subsequently obliged to remove her from the police precinct to the Hospital. It was shown that the policeman on duty and the matron at the station house, both obviously persons whose medical opinion must be of great weight, differed as to diagnosis from the surgeon, of whom it was even insinuated that he was young. The usual dialogues were well written and showed a wealth of inventive genius, but of course failed to agree in the various papers.

The foundation of fact was that the woman, when seen by the surgeon, refused to be taken to the Hospital and wished to go to her home in a cab. When asked by the police for a diagnosis to satisfy the red-tape of the precinct blotter, contusion of the wrist and alcoholism was given, the most probable according to the doctrine of chances. The woman was later removed by the police to the precinct's station and subsequently became worse. When again summoned the surgeon at once took the patient to the Hospital.

As is well known by many, the New York Hospital regards the affairs of a patient in the light of professional confidence as would a private physician, and in this sets an example which might well be followed by others less reticent. For this reason the house staff are not allowed to make any statements for publication, and the official replies to inquisitive reporters are marked by a characteristic brevity which requires elaboration by their recipients before they will satisfy the readers of a yellow journal. To one who knows the number of grains of salt with which these journalistic fictions founded upon fact must be taken, such malicious slander of a surgeon at first excites indignation. A man while simply doing his duty is accused of being the cause of the death of a woman who had declined his aid, and various brutal remarks are credited to him, while his name adorns any convenient cut in the paper's stock.

But why should the episode be regarded seriously by any one? Of course the reporters must live and although at times they employ means beneath contempt, as in this instance, their ludicrous exaggerations add to the gaiety of life. Mark Twain, who cabled in reference to an announcement of his death that the reports in regard to the state of his health were much exaggerated, understood the reporter's nature thoroughly. Unvarnished facts are not marketable. Furthermore, since it requires a hospital training to demonstrate to a physician that a differential diagnosis between various forms of coma and their prodromata cannot be made, in some cases, with much more accuracy than characterizes a newspaper report, why should one of these writers of daily fiction be supposed to realize this fact? And what right has a hospital to refuse to discuss the affairs of patients when a reporter wishes to know them?

FOOD AND DIETETICS.*

Horace Walpole said of somebody that he never made a bad figure but as an author. How fittingly this saying applies to many medical men of note who have taken up their pens in the attempt to communicate the results of their experience is unfortunately only too apparent when one comes to read critically what they have written. In spite of the assiduous endeavors of certain philanthropic medical editors to guide the literary aspirant through the mazes of syntax and authography; in spite of the constant appearance of such estimable examples of the doctor's *vade mecum* as "Polysyllabics Plainly Presented" and "How to Write Though a Physician," the number of really successful medical authors—

*Food and Dietetics. By Robert Hutchison, M.D., Edin., M.R.C.P. New York: Wm. Wood & Co., 1901.

from a literary standpoint at least—is minimal. When, therefore, we come across a book like "Food and Dietetics" and find it fascinating both in matter and manner from start to finish, we cannot refrain from commenting editorially on our find. The author of this really "notable book of the season," Dr. Robert Hutchison of London, is deserving of the highest enconiums as a medical man for presenting to the profession what we consider to be the most noteworthy treatment of a most important subject, which has appeared in a long time, and we offer him our heartiest congratulations as an author for having succeeded in confiding his ideas to paper in a style eminently perspicuous and entertaining. We learn from the preface that the contents of this book were first addressed to the students of the London Hospital in the form of a course of lectures, a fact which impels us to extend to those students our congratulations upon their good fortune.

It is self-evident that no man can be a really good physician who does not know the nutritive constituents and relative values of foods. Such knowledge constitutes in large measure the basis of therapeutics. And yet how many doctors there are who, grossly indifferent to the immense importance of the diet in sickness, content themselves with the mere drug treatment of cases, while they leave the selection of the fuel by which the fires of life are to be kept burning to the discretion of parents or nurse.

It does not take the really wise physician many years to discover the paucity of specifics in his medical armamentarium. Arrived at this degree of sapiency, he expends his efforts in instilling into the minds of those intrusted to his care the great lessons of preventive medicine, and paramount among these the necessity of fortifying the body against the inroads of disease by means of properly selected foods.

To the many who are themselves in need of the knowledge in regard to food and dietetics, which will enable them to deal most satisfactorily with their patients, we recommend Dr. Hutchison's book. In it they will find traditional errors annihilated, cherished delusions dispelled, and in their places solid, well-substantiated facts.

We feel, under the circumstances, that to reproduce some of the very many interesting things of the book would be too much like picking out "gems" from Shakespeare and so refrain. We feel safe in saying, however, that its perusal will satisfy the most critical. Even with regard to such commonplace articles of diet as butter, milk and eggs, the author is able to tell us a great deal that is eminently practical and useful in our daily handling of the sick.

Of particular interest is what he has to say on vegetarianism, alcohol and the cooking of food.

ECHOES AND NEWS.

NEW YORK.

Hospital Opening.—The New York State Hospital for the care of Crippled and Deformed Children located at Tarrytown, N. Y., will be opened Friday, May 17, 1901. Bishop H. C. Potter will preside. Drs. R. F. Weir, A. A. Smith, and W. M. Polk will deliver short addresses.

Columbia University Appointments.—Dr. L. Emmett Holt has been appointed Clinical Professor of Pediatrics; Drs. Evan Evans, D. Bovaird, E. Solley and N. B. Potter, tutors in Medicine. It is announced that Dr. F. Peterson has been appointed Clinical Lecturer of Psychiatry.

East Side Doctors' Club.—Physicians on the East Side below Fourteenth street have formed the East Side Physicians' Club, with headquarters at 165 Henry Street. The membership is 175.

Cornell Medical College Library.—President Schurman has announced that negotiations carried on through the university library officers have succeeded in securing for the Loomis Laboratory of the Medical College the complete pathological library of the late Dr. Felix Victor Birch-Hirschfeld, who was Professor of Pathology and Pathological Anatomy in the University of Leipsic, and Director of the Leipsic Pathological Institute.

Woman's Hospital College Addition.—The trustees of the New York Medical College and Hospital for Women have now sufficient funds on hand to proceed with the erection of the new hospital building to adjoin the present site in West One Hundred and First Street, and the contract will be let in a few days.

New York Academy of Medicine.—A stated meeting will be held on Thursday evening, May 16th. Dr. Stephen Smith will deliver a memorial address on the late Dr. S. S. Purple, formerly President of the Academy. The following papers are announced: "Sitophobia of Enteric Origin and Syphilis of the Liver," by Dr. Max Einhorn; "The Intestinal Intoxication Occurring in Mucous Colitis in Young Children," by Dr. Henry Koplik. Discussions by Drs. Jacobi, Chapin, Northrup, Southworth and others.

Manhattan Dermatological Society.—A regular monthly meeting was held on Friday evening, May 3rd, at the residence of Dr. A. Bleiman, 206 East 48th Street. Dr. Wm. S. Gottheil was in the chair. Dr. R. Abrahams presented a woman with pityriasis versicolor limited to the palms. Such cases were rare, only one other, that of Gottheil being recorded. Microscopical examination of the scales by Dr. Gottheil showed the presence of the *microsporon furfur*. At present the palms showed a superficial scaliness, although before the patient had washed so frequently that there were light and dark yellow patches of various sizes and shapes. Dr. Gottheil remarked that the clinical picture was not as characteristic as in his case, but that the microscopical appearances were classical. Drs. Bleiman and Weiss thought that from present appearances a diagnosis of tellositas or eczema would be more likely. The microscope however settles the diagnosis. Dr. J. Sobel advised the application of Lugol's solution in order to bring into prominence pale and imperceptible lesions (Allen's test). Dr. E. L. Cocks showed two cases of prurigo in native-born children of eight and nine years respectively. Both gave a preurticarial history and presented a papular eruption on the extensors, enlarged glands, and a nutmeg-grater feeling. Dr. R. Abrahams considers both chronic urticaria. Pilocarpine acts well in these cases. Dr. J. Sobel fails to find the picture of prurigo in either case. The papules lack the firmness of prurigo, the characteristic buboes are not present and he cannot detect the feeling of a nutmeg-grater. Both, to his mind, are chronic papular urticaria. Dr. L. Weiss would call both cases lichen urticatus or chronic lichen simplex. The patients lack the anemic, haggard look and the buboes of prurigo. Dr. Obendorfer says neither case looks like prurigo. He misses the great infiltration of the skin, the firmness of the individual lesions and the adenopathy. He would call them chronic papular eczema. Dr. Gottheil remarked that he inclines toward a diagnosis of prurigo. The picture is characteristic neither of prurigo nor papular urticaria. Dr. L. Weiss presented a patient with *eczema neuroticum vegetans* of the lower extremities. There were patches with somewhat healed centers, the individual lesions consisting of small papules simulating lichen planus. Dr. E. L. Cocks considers it lichen planus plus eczema. Dr. Obendorfer calls it eczema. Dr. Bleiman thinks it primarily pruritus senilis. Dr. J. Sobel would call it mycotic eczema on account of the more or less sharply-defined edges, the somewhat circular form, the healed centers and the persistency. Formalin and chrysarobin act well. Dr. R. Abrahams calls it parasitic eczema. Strong nitrate of silver solutions (50 per cent.) and carbolic acid are recommended. Dr. Kinch thinks it an eczema. Dr. Gottheil stated that the papules are typically those of eczema. Dr. L. Weiss showed a woman with *rosacea* of the cheeks. Stretching of the skin enables one to see the capillary circulation. Dr. Geyser advised treatment with the negative galvanic needle inserted at right-angles into the vessels. Dr. Bleiman presented a case of favus of the nails. The scalp showed evidences of favus. Dr. Oberndorfer showed a probable *acne varioliformis* of the scalp, with numerous bald spots. Dr. R. Abrahams would diagnose acne vulgaris and folliculitis. Dr. E. S. Cocks sees no acne varioliformis. Dr. J. Sobel finds acne pustulosa and folliculitis abscedens. Dr. L. Weiss states that the bald regions speak for folliculitis decalvans. Dr. Ochs presented a patient with resolving syphilis. Dr. Bleiman presented a pityriasis rosea resembling seborrheal eczema and demonstrated the continuous treatment of scabies with Wilkinson's ointment.

The Late Dr. F. J. Brockway.—At a recent meeting of the West End Medical Society the following minute was adopted: "The members of the West End Medical Society desire to express their sorrow at the death of their fellow-member and former President, Dr. Fred J. Brockway. This is to be taken not merely as a formal record of the feeling of the Society as a body, but as the expression of a genuine sense of loss on the part of each individual member.

"While the death of our colleague makes us regret the loss to the profession of his solid abilities as a practitioner and teacher, on the other hand, his sterling qualities as a man and friend, his absolute reliability, his sound common sense and last, but not least, his fund of quiet humor, all constitute a claim to the personal regard of each member of the Society such as to call forth that regard in its highest form. The Society wishes Dr. Brockway's family to know of the great esteem it had for him and it hereby expresses to them its deepest and most heartfelt sympathy.

"*Resolved*, That the above minute be entered in full on the records of the Society and that a copy be sent to the family of our deceased colleague.

"Bern B. Gallaudet, M.D., James E. Newcomb, M.D., Committee."

PHILADELPHIA.

General Anesthesia in Heart Disease.—The May meeting of the College of Physicians was devoted to the discussion of the relation of diseases of the heart to surgical operations, especially to the use of general anesthesia. Dr. W. J. Mayo, of Rochester, Minn., spoke of preëxistent heart disease in reference to surgical operations. Dr. Mayo said that the reverse power of the heart must be taken into consideration in all cases. He has found this to be greater in old age than in infancy. Valvular lesions in persons between the ages of ten and forty are usually well compensated and anesthetics generally cause little risk. Later in life myocardial change is usually associated with valvular lesions, many of the sudden and unexpected deaths occurring soon after operation being due to such change. A

knowledge by the surgeon and anesthetizer of the presence of cardiac lesion is a great safeguard against danger.

The Safest Anesthetic to Use in Organic Disease of the Heart and Vessels.—Dr. H. A. Hare spoke on this topic, saying that the majority of accidents in these cases were due to the shock of operation instead of the anesthetic. The condition of many such subjects improves under an anesthetic. The ordinary clinician and surgeon does not pay enough attention to the vessels, being satisfied with examining the heart. The cardiovascular tone and blood-pressure are all-important questions. Ether, although the safest anesthetic we have, is contra-indicated in some cases of high arterial tension. American surgeons do not often enough employ atropine for its effect on secretions. Oxygen and an anesthetic should never be given by allowing the gas to bubble through the anesthetic. An increase or decrease of oxygen means the same effect on the anesthetic. Each should be given alone. General anesthesia is better than local or spinal anesthesia in valvular or myocardial disease. Dr. Hare believes that anesthesia by intraspinal injection will soon be a medical curiosity.

The Cardiac Complications Which May Arise During Operation.—This paper was read by Dr. J. M. T. Finney of Baltimore. He finds that the so-called heart cases bear ether well. Fatalities occur more frequently under inexperienced anesthetizers. Heart disease of itself does not contra-indicate the use of ether. Chloroform is especially dangerous in cases of myocardial change. The contra-indications to ether are respiratory rather than cardiac. Anesthesia is dangerous when the hemoglobin is under 30 per cent. Dr. Finney has studied 150 cases of heart disease and the effect of anesthetics upon them. The only appreciable bad effects were in cases of myocardial change. He has the anesthetizer keep a chart of each case, showing the pulse frequency each five minutes.

Cardiac Complications Which May Arise After Operation.—Dr. Alfred Stengel spoke on this topic. Inferences regarding this question should be drawn from simple examinations under anesthesia or from minor operations. In gynecological cases the heart should be studied before and after the operation. Myocardial disease is common in cases of myoma of the uterus. Terminal pneumonias ascribed to aspiration or irritation are often due to failing circulation and the anesthetic is only the exciting cause. Pulmonary embolism is more frequent after gynecological operations.

CHICAGO.

Woman's Medical College.—At the annual meeting, held April 24th, Dr. Eliza H. Root was recommended for Dean of the College during the absence of Dr. Marie J. Mergler, who is away on a sick leave. Dr. John Ridlon was elected Secretary of the Faculty.

Sentence of a Midwife.—A midwife was found guilty of murder and sentenced to fourteen years in the penitentiary. The offense was the common one of criminal abortion. The patient died.

St. Luke's Hospital.—This institution is a beneficiary under the will of the late Mrs. Jennie L. Young, to the extent of $5,000.

The Kerr Bill.—This bill, which required all manufacturers of patent medicines to print the formulæ of their productions on the bottle or wrapper, and also to designate whether the medicines contained any harmful drugs, was defeated in the Senate.

Cook County Hospital Investigation.—The Committee, which has been investigating the charges of general bad management, neglect and cruelty at the Cook County Hospital, has submitted its report, and finds the charges not sustained. Many of the charges were built up on the most flimsy pretexts. These were carefully probed by the jurors, who gave several days of their time to this work alone. The report makes several recommendations for the benefit of the Institution, particularly with regard to the heating and ventilating systems, and praises the work of the nurses whom it terms a body of "faithful, conscientious and able women." The investigation into the working conditions, however, brought the jury to the conclusion that the nurses are much overworked, and the following comment was made on this point: "It would seem that such increase as is possible in the staff of nurses would greatly relieve the faithful women now doing this work, and would also result in more comfort to the sick, insuring to them many small attentions which are now impossible." Attention is called to the fact that the food served to patients had been condemned by several witnesses, but the report states that an examination of the supplies at the hospital showed them to be good and wholesome. Most of the complaints are ascribed to poor service and lack of variety. A tribute is paid to the internes, who are described as "bright young physicians, who have won their positions by competitive examination." After paying this compliment, the report continues: "Although most of the evidence heard would indicate that the internes are entirely subordinate to the attending physicians, we think that their desire for knowledge and experience in many cases outweighs their regard for hospital rule and for conservatism in the treatment of patients." The remedy suggested for this is the appointment of a house physician to supervise the medical part of the hospital work, if the three schools of medicine could agree on a capable man. A decrease in the number of doctors on the attending staff and the formation of a more perfect organization are also urged. The excellent operating-rooms and management of clinics are warmly praised in the report, and the management of the hospital is congratulated on the state of perfection to which these details have been brought. Finally, the report states: "While

we have ventured to criticize much in the condition and management of the hospital under the present *régime,* we think that the main shortcomings of all our county institutions are due largely, if not wholly, to the pernicious influence of politics and politicians in municipal affairs."

Chicago Medical Society.—At a clinical meeting, held May 1st, Dr. John B. Murphy exhibited a patient upon whom he had performed an abdominal colopexy for prolapse of the rectum. He also reported cases of lymphosarcoma of the mesentery, excision of the intestine for malignant disease, and Pott's disease. Dr. E. Wyllys Andrews reported cases of gastrostomy, umbilical hernia, strangulated scrotal hernia, tendon suturing, nephrectomy for malignant disease, renal calculi, tetanus, cerebellar tumor, and laparotomy for perforation of the intestine in a case of typhoid fever. Dr. Wm. E. Morgan exhibited a case of goiter complicated by stenosis of the trachea. Dr. George W. Webster showed two cases of weak heart and, after giving briefly the histories of the cases and the physical findings, he discussed the etiology and prognosis in cases of weak heart.

Chicago Pediatric Society.—At a meeting, held May 2nd, the following officers were elected: President, Dr. W. S. Christopher; Vice-President, Dr. J. W. Vanderslice; Secretary and Treasurer, Dr. Emma M. Moore; Trustee, life member, Dr. John C. Cook; Trustee, short term, Dr. D. W. Rogers, and Trustee, three years, Dr. Alfred C. Cotton.

Pathology of Ulcer of the Stomach.—Dr. William A. Evans discussed the pathological anatomy and histology of ulcers of the stomach. As to location, the seats of ulceration are the lesser curvature, the posterior surface, and near the pylorus. Occasionally the duodenum and the esophagus are the seat. The analysis of 7,700 autopsies by Stawell would indicate that ulcer of the stomach is about as frequent in men as in women. Gluzinski says the majority of the ulcers occur in the men. The usually accepted figures are about twenty times as often in women as in men. Greenough and Joslin, as a result of a study of the cases in the Massachusetts General Hospital from 1888 to 1898, conclude that it is four times as frequent in men as in women. Saundby says it is twenty times as frequent in women as in men. Hyperacidity and ulcer of the stomach are generally associated. The speaker's opinion is that the hyperacidity results from the continued irritation of the ulcer, and not the ulcer from the hyperacidity. In many cases of marked hyperacidity in a young woman, ulcer as an etiological factor is to be borne in mind. In ulcer of the duodenum no hyperacidity of the gastric juice can be demonstrated as a general proposition.

Among the other etiological factors recognized are embolus and thrombus. The anatomical arrangement of the celiac axis and of the gastric artery would make embolus infrequent. Besides, embolus is not common in people presenting the clinical picture manifested by a case of ulcer of the stomach. Thrombus can frequently be demonstrated.

That there is a relation to chlorosis is beyond question. Again, there is the difficulty of deciding which is the primary lesion. On the one hand, the loss of blood and, perhaps more important still, the direct absorption through the ulcer of incomplete digestion products can produce chlorosis. Usually the degree of anemia bears some relation to the loss of blood. On the other hand, women with ulcer of the stomach usually give a history of anemia preceding the ulcer. The same is not true of men. The ulcer does not repair until the anemia is lessened according to Fütterer. This might be true, and the chlorosis be only a contributing factor. Hemmeter and Stokes have collected 21 cases of syphilitic ulcer in the literature up to 1900. As to the relation of ulcer to carcinoma, Fütturer holds that carcinoma develops right in the ulcer as a result of physical injury. It develops on the side of impact.

Treatment of Ulcer of the Stomach.—Dr. James B. Herrick read this paper. He said that many of these ulcers heal spontaneously. The conditions that tend to keep up the process are the general chlorotic state, the local circulatory condition, but above all, the irritation from food which excites peristalsis and vomiting and causes an outflow of the hyperacid gastric juices. Theoretically, the best results should be obtained from the treatment securing most nearly perfect rest of the stomach, including freedom from peristalsis, from movements of the viscus, and attending movements of the body. Experience shows it to be true, that the more nearly these ideal conditions are met the better the result. Drug treatment is unsatisfactory. Treatment by light or milk diet gives better results. The results of Leube and others who employ his method are by far the best. Leube puts his patients to bed, applies hot applications over the epigastrium, and gives a minimum amount of carefully-selected food with occasional drugs to correct hyperacidity. Absolute rest in bed of from two to six weeks was advocated. Nothing should be allowed by the mouth, not even water, for from three days to three weeks. Nourishing enemas should be given at regular intervals; a cleansing enema of water given every morning; gradual substitution of liquid by the mouth for the enemata could be allowed when the pain, tenderness and vomiting had entirely ceased. It was better in all cases, if possible, to keep the patient on rectal feeding for at least one week. Light diet should be continued many weeks after the patient had left the bed. Attention should be given to the anemia preferably by the administration of iron. The results of the treatment were almost immediate disappearance of the nausea, vomit-

ing, and pain, and a rapid lessening of the tenderness on pressure. Hunger, thirst and sleeplessness were scarcely complained of after the first twenty-four hours. Emaciation and weakness rapidly disappeared when the feeding by the mouth was begun. In recent cases of ulcer a cure could be quite confidently predicted. In older cases of months or years standing there was generally an improvement, occasionally a cure. Certain cases were clearly surgical, chiefly those with alarming severe hemorrhage, or repeated small hemorrhages, not disappearing under rest and rectal alimentation; also cases of perforation, with peritonitis; cases complicated with adhesions, perigastritis, dilatation, etc., and cases with obstinate vomiting, or severe pain that resist the treatment by alimentation. Believing that other methods of treatment were unsatisfactory and that this method by breast and rectal feeding offered the most favorable conditions for the natural healing of the ulcer, that it was safe, practicable and efficacious, he believed it should be tried in all cases and not reserved for the complicated or desperate ones.

GENERAL.

Dr. Vaughan and Women Students.—It seems that the daily press has been making much of some remarks of Dr. Vaughan relative to female medical students. From authentic sources it is learned that Dr. Vaughan did not make the remarks that have been attributed to him.

Imported Rats Die of Plague.—Secretary A. C. Young of the State Board of Health says that a case of bubonic plague was discovered a few days ago in Waldoboro, Me., in some pet rats brought from the Philippines by a soldier.

Honor to Dr. Chaillé.—Dr. Stanford E. Chaillé, Dean of the Medical Department of Tulane University in New Orleans, has been given the degree of LL.D. by the University on his completion of fifty years in its service.

Brain Topography.—Prof. Gustav Retzius of Stockholm, in a new issue of his *Biologische Untersuchungen,* publishes an interesting paper on the brain of Mme. Sonya Kovalevski, the eminent Russian mathematician, who was born in Moscow in January, 1850, and died in February, 1891, seven years after her appointment to an associate chair of mathematics at the University of Stockholm. Professor Retzius finds in the brain of this gifted woman no marked departure from the ordinary type of brain-structure, it being of the normal form found in women generally, although of rather small size and of limited complexity. Of a certain interest is the shortening of the Sylvian fissure, a feature which was also distinctive of the brain of the mathematician Gyldén. Professor Retzius, as a result of his researches, is not disposed to deny the interesting conclusion latterly reached by Professor Möbius that the "mathematical centrum" is situated in the lateral parts of the frontal lobes of the brain—a view with which the condition of the brains of Gyldén and Kovalevski in no way conflicts; but he considers our knowledge of the subject too limited to permit as yet of a definite conclusion being arrived at. Rather would he believe that this problematical centrum is situated in the parietal region of the brain.

Strike of Physicians.—The physicians' strike in Germany, noted in a recent issue of the Medical News, arose in connection with the system of sickness insurance, by which some thirty million Germans are entitled to free medical attendance on payment of a small sum. Theoretically, nothing could be more perfect than such a coöperative arrangement. Practically, it has been found that the interests of the sickness bureaus (*Krankenkassen*), the doctors, and the patients clash at almost every point. The bureaus endeavor to promote economy, and desire that few cases of sickness shall be reported. The people feel that the doctors treat them unfeelingly. The doctors, on their part, find the bureaus hard taskmasters. In Leipsic the conflict has declared itself frankly. The bureau physicians, as in other cities, had organized an association to represent the profession. This commission attempted to negotiate with the bureaus for better terms and less irksome conditions of service. The bureaus refused to deal with the commission, but were willing to hear individual complaints. It was the old question of "recognizing the union." The doctors did just what workingmen do under the circumstances—struck, and the work of the Leipsic Bureaus is crippled.

At Munich the case of the doctors was still harder. Their average profits from the Bureau service were about $75 yearly. The pay was the same for the most difficult and for the lightest cases. The united effort of the physicians raised the average pay for a call to about fifteen cents. They demanded as well a special tariff for obstetrics and other difficult operations, and when such recognition was refused, like their Leipsic brethren, they struck in a body. The case would hardly call for comment were it not that patients are equally disaffected. The system oppresses them. They must take such physician as is allotted to them, and must buy their medicines at certain pharmacies, or lose the benefit of their subscription. They receive underpaid treatment grudgingly given, which is the worst treatment. They possibly lose more in equanimity than they gain in economy. While it is possible that some reform of the system may be secured, it looks very much as though its defects were radical. Organization fails when it clashes with human nature, and it is hard to see how any bureau system is consistent with the human relation that should exist between physician and patient.

Obituary.—Dr. Irving C. Rosse, a well-known physician and surgeon of Washington, D. C., died there last Friday of hydatid obstruction. He was fifty-four years old. He was a specialist in mental diseases, author of several

medical books and was a witness in the Guiteau and other famous trials.

Dr. Samuel Kuypers Lyon, who died in New York on Saturday, was born August 24, 1841, in that city. He was graduated in 1860 from Columbia College, and studied medicine under Dr. Willard Parker. He was graduated from the College of Physicians and Surgeons in 1866, serving sixteen months as junior and senior in the New York Hospital. He was appointed Attending Physician of the Heart and Lung Department of the New York Dispensary. He was a member of the County Medical Society, the Academy of Medicine, the Alumni of Columbia College, and the St. Nicholas Society.

Dr. George C. Jarvis, Surgeon of the Seventh Connecticut Regiment throughout the Civil War, and for many years a consulting physician of the Hartford Hospital, died Tuesday at Hartford, Conn., of pneumonia. He was sixty-seven years old.

American Hospitals in Pekin.—An English correspondent to the *British Medical Journal*, April 13th, comments in a manner very pleasant to Americans on the United States Hospital service at Pekin: "One fact which is realised as soon as one enters the hospital is that the medical arrangements in the American army possess a far higher degree of importance than in our own. The hospitals are not only given the best sites available, as is assumed to be the case in our army, but the amount of skilled labour supplied for employment under the direction of the chief medical officer is as unstinted as the funds placed at his disposal. Combatant officers good humouredly complained that (it's no use trying to get a nail knocked in anywhere else until the hospital is finished.) It was a surprise to most of us to find that every single American soldier on active service has a folding bedstead issued to him, no matter what his rank may be. His diet on active service contains luxuries and delicacies the names of which are scarcely known in our Commissariat Department—personally, I think our Commissariat are to be congratulated, for the diet of our soldiers is in my opinion superior in nearly every way to that of the American army, and more suited to the requirements of a campaign—but it is not till the American soldier goes to hospital that he is really in a position to appreciate how much his Government loves him. I do not think it would be a serious exaggeration to say that the American Hospital in Pekin could hold its own in every respect with most London hospitals. Bedsteads, bedside tables and chairs, brought from America, a 'diet kitchen' at the end of the ward, with an ample cooking range and a highly-trained cook in a white apron and cap, whose life's business is cooking, and who is not expected to do anything else. He is not an enlisted soldier, and he may not know one end of a rifle from another, but he can turn out any known delicacy that ever tempted the appetite of a worn-out patient. I lay stress on this, as indeed any one would who saw those business-like diet kitchens and cooks with a lavish supply of all the apparatus, materials, and paraphernalia that a *chef* could desire The difficulty of supplying really good food to the sick on active service is a great one, but the American Government, by simply recognising this fact, and by making an extra outlay to meet the difficulty, in a large measure overcomes it."

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, April 27th, 1901.

THE SOUTH AFRICAN WAR—A METEORIC SHOWER OF HONORS—THE STAR-SPANGLED PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS—THE COST OF THE CONSULTING SURGEONS TO THE FORCES—A SLIGHT ON THE DIRECTOR GENERAL OF THE ARMY MEDICAL SERVICE—THE ORDER OF THE BOOT—LORD ROBERTS AND THE ARMY DOCTORS—DEATH OF A MEDICAL M. P.

The great event of the week here has been the distribution of honors for service in the South African war. The *London Gazette* (which is the official channel for the publication of such intelligence) appeared on the evening of April 19th, and the list of those whom the King delighteth to honor on this occasion extends over thirteen pages. I say "on this occasion" because the end is not yet. The present list includes only the honors given for services rendered when Lord Roberts gave up the supreme command of our forces in South Africa. There are more to come when Lord Kitchener sends in his account. In the meantime we have hardly recovered from the dazzling effect of the meteoric shower of crosses, stars and flamboyant ribbons which have lit up the normal dulness of the British sky. It will soon be almost a distinction here, as it was in the case of Lord Castlereagh amid the multi-decorated diplomatists at the Congress of Vienna, not to have an order or a title of some kind. At a time when there was an epidemic of Royal Commissions, Sydney Smith said that on any given citizen there lay the *onus probandi* that he was not a Commissioner. At present you can hardly meet a man in the street who is not a C.B. or a C.M.G.

The medical profession has got its share of decorations which like the rain have fallen on the just and on the unjust, for it must be admitted that some of the distinctions must be regarded either as sops to some Cerberus, colonial or other, than as rewards of merit. But on the whole they have been well earned. There are cases in which the recognition seems scanty. Sir William MacCormac, who was expected to get a peerage, has to be content with a K.C.B.

(Knight Commander of the Bath), a superfluous distinction as it only carries with it a title which he already had. It does, indeed, add a decoration to the many others which makes the President of the Royal College of Surgeons when in full war-paint more star-spangled than the American flag. He is a man of fine presence and his manly bosom offers an expanse for the use of which enterprising advertisers would doubtless pay fabulous sums. But he already must find it difficult to find room on it for his decorations, and if he gets many more, he will have to hang some of them on his back. A sandwich-man with decorations instead of boards—that would indeed be an advertisement of royal favor more striking than being clad in the royal apparel and riding the King's horse!

Apart from his amiable weakness for titles and decorations, Sir William MacCormac is a most worthy man. If he is not a great surgeon he has done the work that has come to his hand faithfully and well. He stands high in the favor of the sovereign. At St. Thomas's Hospital where he was long the ruling spirit he was respected by his colleagues and liked by the students. He is popular with the profession and in spite of the honors which have fallen to him, he has no enemies—partly perhaps because he is not feared as a rival. In fact, though his name has always been much in the mouths of men, he has never had a great practice. He is rich and has no family and has therefore been able to pursue his policy of "peace with honors," free from the disturbing influence of sordid cares.

The other eminent men who went out to the seat of war as Consulting Surgeons to the Forces have to be content with the C.B. (Companion of the Bath). In this batch of surgeons of world-wide reputation like Frederick Treves and William Watson Cheyne are lumped together with promising young men whose names were before the war altogether unknown to fame. They had the wit to take at the flood the tide which leads on to fortune, and they have their reward. They did excellent work, though it may be doubted whether their services were worth the remuneration, at the rate of $25,000 a year, granted them by a grateful country. The sending out of consulting surgeons was in the first instance due to the pressure brought to bear on the War Office by influential persons who distrusted the professional capacity of the ordinary army doctor, and were anxious that the "curled darlings" of the Guards and other crack regiments in whom they were interested who might have the mischance to get a Boer bullet lodged in their dainty persons should have the best surgical craftsmen to heal their wounds. Then a generous rivalry sprang up among our surgeons, who all wished to place their knives at the disposal of their country. National susceptibilities had also to be soothed, as Scotland and Ireland were protesting against England being the favored nation. The end of the matter was that seven consulting surgeons were sent out at the public expense, besides a number of volunteers. It is by no means clear that this galaxy of surgical talent has done much more for the wounded soldiers than could have been accomplished by the medical officers of the Army; and it is thought by some who are in a position to know the facts that the vast sum of money spent in rewarding the patriotic services of the consulting surgeons would have been expended to much better purpose in improving the efficiency of the Royal Army Medical Corps.

The army doctors have had a tolerable share of distinctions, but there is great dissatisfaction at the pointed omission of the name of the Director-General of the Service from the list. The reason doubtless is that the medical organization of the campaign has been fiercely criticized by Mr. Burdett Coutts and others. The Royal Commission on South African Hospitals found that in no previous war had the medical arrangements been so good, and the credit of these arrangements belongs mainly to Surgeon-General Jameson whose reward is to have what is nothing less than a public affront put upon him by the War Office. Our present Secretary of State for War, Mr. Brodrick, poses as a strong man, and he is believed to have for some reason or other, a feeling of hostility towards the medical service. He has dealt very severely with some medical officers of high rank whom he holds responsible for the hospital "scandals" which gave notoriety-seeking critics a handle. Two or three medical Colonels have, it is understood, received instead of the C.B., the "Order of the Boot," and have besides had the pensions to which in the ordinary course they would have been entitled on retirement docked to the amount of 20 per cent. It is whispered that Mr. Brodrick was with difficulty restrained from "breaking" one distinguished officer. All this is creating a feeling of unrest and fear for the future among our army doctors.

It is noted that although Lord Roberts mentions several individual officers with commendation he has no word of praise for the R.A.M.C. as a whole. This is all the more remarkable from the lavish display of eulogistic epithets that he makes in referring to every other branch of the army. Here too may be traced the effect of the violent and too often unscrupulous attacks that have been made on the medical service. By the way, Lord Roberts has been publicly claimed by the homeopathic sect as one of their scientific, or rather unscientific, persuasion. I do not mention this as having any particular bearing on the subject, but as a matter of some psychological interest.

Dr. Tanner who was referred to in a recent letter as one of the medical Members of Parliament has since died. His case was so hopeless when I wrote that, but for the decencies of journalism, he might have been spoken of in the aorist tense. One of our lighter poets, Praed, who was also a Member of Parliament, said that he found our grave legislators "but Eton boys

grown heavy." Of Dr. Tanner it may be said that to the end of his life he was but a medical student grown heavy. His voice was often enough heard in Parliament, it is true; but it was in cockcrowing and bawling out insolent interruptions. On one occasion when the Speaker, for some high constitutional reason or other, left the Chair, Dr. Tanner deposited himself therein, to the horror of the stolid Britons present, and to the scandal even of the Irish Members who did not care to see their cause disgraced by horse-play. As a representative of the medical profession in the House of Commons, Dr. Tanner was worse than useless, for unlike his countryman, Goldsmith, he *dis*adorned whatever he touched. He is said by those who knew him to have had a warm heart, but, unfortunately, he had a head which was not only hot but empty.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, Held at Baltimore, Md., May 7, 8, and 9th, 1901.

First Day—May 7th.

The Cancer Problem.—At the close of the Executive Session and after the introduction of Mr. Mayo Robson, F.R.C.S., of Leeds, England, the President, Dr. Roswell Park, of Buffalo, delivered his Address. It was, in considerable measure, a repetition of Dr. Gaylord's recently published paper. In very generous criticism of the methods employed by earlier investigators, Dr. Park emphasized the coördinate importance of anti- and postmortem examinations. Each of these seem to point with equal clearness not alone to the infectious, but to the parasitic character of the neoplastic infection. At present there are three leading theories as to the etiology of cancer. Each one is championed by a nation, to the French it is a protozoon to the Italians, a yeast; to the German, a cellular degeneration. It has been said that the long duration of the period of infection is a bar to the acceptance of the parasite theory. This seems groundless. In the New York State Laboratory was first firmly established the fact that a disentanglement of the complex problems enshrouding the etiology of neoplastic growth could be reached only through the combined efforts of biological and chemical methods of investigation. By this marshaling of their forces, Dr. Park and his colleagues concluded that the parasite is a protozoon, although as yet it is not as positively proven as it doubtless will be in the near future. Another point gained relates to the ultimate cause of death. Their chemico-biological researches prove this to be due to what he calls a "terminal infection"; a toxemia; a hematogenous infection.

Polymorphism of Parasite.—Of special interest and import is the polymorphic character of the parasite. Suspended in a hanging drop on a warm stage these varied changes can be watched until a terminal state is reached which closely simulates sporulation. Another point to which the President directed attention is the extraordinary increase of the organisms at the time of death and the ease with which, at this moment, they may be demonstrated in the blood. What of the yeasts, and the cancers produced with them by Sanfelice? In all justice it must be said that this careful Italian without doubt produced malignant growths by the yeast organisms, but Park feels that his percentage of successes were in no way comparable to those obtained at Buffalo, where, out of 14 guinea-pigs injected with parasites from *human* source, death ensued in all within fifty days; injections with organisms which had once killed a guinea-pig death resulted in twenty-five days. These injections are bacteriologically sterile; they show the organisms to be capable of an increase of virulence.

In concluding Dr. Park drew attention to the similarity between carcinoma and tuberculosis. Each begins locally: each kills by becoming general; early operation may save life in each. Sarcoma and carcinoma are due to different varieties of the same organism. Just as we now recognize three types of the malarial parasite, doubtless as many, or more exist of the parasite of neoplastic growths. Spontaneous retrocession of malignant development is probable, and is in no way incompatible with the protozoon theory of this disease.

Early Signs of Carcinoma of the Uterus.—In a highly interesting extemporaneous talk, Dr. Thomas S. Cullen of Baltimore discussed the methods employed at the Johns Hopkins Hospital of establishing an early diagnosis of uterine carinoma by the investigation of curette scrapings. He called attention to the three varieties of uterine epithelium each of which gives rise to its special form of carcinoma, and stated that the presence of large, coal-black cells in otherwise normal epithelium were pathognomonic of malignancy. His remarks were illustrated by a series of beautiful microphotographical lantern-slides.

Brief Considerations of Cancer of the Breast Treated at the Johns Hopkins Hospital Since 1889.—Dr. W. S. Halsted of Baltimore declared that the differences existing between the closely allied neoplastic growths are so subtle as to elude the most painstaking artist, nevertheless he is trying to get pictures which will show the different forms. Of 320 cases of cancer of the breast, of which 150 are not yet three years old and which he therefore excludes, he presented an interesting series of tables. In 450 cases of breast tumors he found but three to be sarcomata, one primary; one secondary to the tonsil, and one to the uterus.

His malignant cases he tabulated as follows: Class I., cervical and axillary glands removed at first operation; class II., axillary glands removed at first operation; cervical at second; class III., cervical glands not removed.

His results were as follows: Class I., local recurrence in 11 per cent.; class II., local recurrence in 20 per cent.; class III., local recurrence in 9 per cent.

His cured cases present the following percentages: Class I., 45 per cent.; class II., 33 per cent.; class III., 43 per cent.

Late Results in Inoperable Sarcoma Treated with the Mixed Toxins.—As to the preparation of the injection fluid, Dr. Wm. B. Coley of New York had nothing new to suggest. It now seems to have reached a certain degree of perfection in that it is practically without danger, if properly used, to any except profoundly prostrated cases. If, in sarcoma—and there seems little indication for its use in carcinoma—there is no evidence of improvement at the end of three or four weeks the case may well be considered hopeless. Recent statistics compiled from the observations of many investigators, combined with his own, give the following percentages of cures: Round-cell sarcoma, 3-4 per cent.; spindle-cell, 50 per cent. The results are *nil* in melanotic and lymphosarcomata. Dr. Coley drew the following conclusions: The mixed toxins should be injected as prophylactic in *every* case of post-operative sarcoma. The treatment is rarely curative in carcinoma. The parasitic theory of malignancy is supported by the behavior of cases injected with the toxins.

Influence of Mental Depression on the Development of Malignant Disease.—In an interesting and instructive recess from the present, Dr. Joseph D. Bryant of New York traced the history of cancer from its earliest cradling by the Grecian observers to the most ultimate modern views. The Greek, with characteristic power of insight, plead rather for a physical than a mental cause in the etiology of cancer. In the darkness of the subsequent ages nothing is heard, until, with the awakening of learning, Ambrose Paré (1510) states "anger makes cancer more fierce and raging." Later, Sir Astley Cooper championed the psychopathic theory warmly and, while Velpeau denied it, Virchow and Rokitanski admitted it, with certain qualifications. Napoleon and Grant—each the victim of extreme mental depression—may have been examples of Paré's theory. These and other conditions led Dr. Bryant to look into the matter from a statistical standpoint. From a careful perusal of the death records of England, Scotland, Wales, Paris and New York, as to the relation which mental depression, as best exemplified in melancholia, he reaches the following conclusions: Of 4,458 insane cases 402 females and 343 males were melancholic; one male and four females had cancer. This shows a percentage of less than one. Out of over two million general deaths 3 died of cancer, males, 4.73 per cent.; females, 8.18 per cent., the ratio here being almost double and the average being 6.42 per cent. Thus it appears that malignancy is six times as frequent in the general community as among melancholics. Moreover, at Ward's Island $^1/_{25}$ per cent. of female melancholics are afflicted with cancer, while the rate rises to ½ per cent. in other forms of insanity. It appears, therefore, that if in melancholia, which typifies the limit of mental prostration, malignant disease is so rare, the belief that psychopathic factors play any etiological part in this dyscrasia is doubtless without foundation.

Dr. J. Collins Warren of Boston, in opening the discussion appreciated the extreme difficulty of approaching so unknown and subtle a question. He felt greatly encouraged at the wonderful display of scientific life which is taking form the country over, in the erection of laboratories devoted exclusively to the study of malignant disease. Especially he wished to compliment the New York State Legislature for their generosity in this regard. He cordially agreed with Dr. Park, in that cancer is no doubt infectious, but he called attention to the fact that, as yet, Koch's laws have not yet been applied to the supposed protozoon. He pointed out that most of the experimental work has been accomplished by inoculation. Danger lies in this, that it may constitute a sort of grafting process: an artificial metastasis. The culture of the protozoon at Harvard has so far been negative. When inoculation results have been positive, has the fluid in every way been safeguarded against contamination? The blastomycetes have recently been beautifully demonstrated by Plimmer, and there is no doubt that they have produced granular connective tissue growths. He feels assured that primary and secondary cancers may disappear, this due to the fact that occasionally katabolism and its accompanying degenerations may exceed anabolism. As a means of more intelligently discussing the results of operations on the breast he suggests the division of these cases into three classes, (*a*) favorable, (*b*) unfavorable, (*c*) palliative. While admitting that Coley's fluid had proved negative in the hands of most operators, he urged the continuance of its use and the encouragement of a treatment which afforded to the hopeless even a single ray of light.

Dr. Thomas S. Cullen of Baltimore in discussion said that although the statements of Drs. Park and Gaylord were very alluring and despite the fact of his having seen some of the latter's most exquisite slides, there yet remains much to be said and done ere the protozoon theory can be considered established.

In closing the discussion, Dr. Park, with characteristic diffidence, admitted the poignancy of these criticisms, but felt certain that within a

short time they would all be happily disproved.

Blood Examination as an Aid to Surgical Diagnosis.—Dr. J. C. Bloodgood of Baltimore asked and answered the following interesting questions: Does the blood afford any constant variation in any of its factors which can be of use in diagnosing the complication of intestinal rupture in severe abdominal contusions? If this exist, it has not, as yet, been discovered. Another problem upon which the blood again throws no light is the differentiation between shock and internal hemorhage. From the blood, however, we do obtain a very sure contra-indication to operations which are not imperatively called for this is a low hemoglobin reading. Fifty per cent. or less should in this class of cases contra-indicate the operation until, by the administration of certain drugs, it can be brought more nearly to the normal. Of special interest were his remarks on post-operative leucocytosis; this he considers a positively assured fact. While leucocytosis also occurs with invariable certainty in intestinal obstruction and peritonitis, in the former it is of the profoundest value because life can almost always be saved by early operation. This of course is not true of peritonitis. In concluding he admitted that even a very high degree of leucocytosis is not *per se* pathognomonic. It is, however, at least as important as T.P.R. and may justly be considered to be of greater value than any one of the three. A leucocytosis exceeding 20,000 twenty hours after the onset of an attack constitutes a faithful guide to prompt operation no matter what may be the clinical symptoms.

Clinical Value of Blood Examinations in Appendicitis.—Dr. J. C. Da Costa, Jr., of Philadelphia presented a report of 118 cases upon which he had operated. He felt that a simple classification always afforded clearness, and he therefore divided his cases into two types, namely, (1) non-purulent, simple and catarrhal; (2) purulent, with or without gangrene and peritonitis. In all but 38 cases there was pus. The hemoglobin averaged about 70 per cent. in the 118 cases; in Class 2 it occasionally fell to 30 per cent. The red cells are usually present in about normal number in both classes. This is not in accord with the accepted belief. Although in some isolated cases the color index has actually approached that found in pernicious anemia, it averages .82. Whatever variations and irregularities may exist, the leucocytosis is constant in Class 2—the only factors which can interfere with this manifestation being the so-called "walling off" and, though very rarely, extreme exhaustion. Dr. DaCosta summed up as follows: (1) The hemoglobin reading in the average case averages about 70 per cent.; erythrocytes, 4,500,000. Profound anemia may contra-indicate operation. (2) There is a moderate leucocytosis with or without pus. (3) A leucocytosis below 20,000 does not call for operation. (4) A leucocytosis of 20,000 or more occurring within twenty hours of the first attack indicates pus and immediate operation. (5) Failure of the leucocytes to return to normal after operation indicates the probable presence of pus pockets.

Blood Examination in Relation to Surgical Diagnosis.—Dr. J. B. Blake of Boston, on behalf of himself and his two collaborators, Drs. J. C. Hubbard and R. C. Cabot of Boston, said that after a series of experiments, conducted with a view of determining the presence or absence of an ether leucocytosis, they had decided that it rarely, if ever, existed. Thirty-six hours after operation, all post-operative leucocytosis has vanished. In uncomplicated fractures the count rarely exceeds 12,000. A singular fact established by that series of experiments is the hemoglobin gain after neoplastic excisions, this being contrary to the accepted belief. The prognostication of typhoid perforation remains still in the dark, the so-called "wave" being of no significance. The hemic changes following prolonged, violent, muscular exercise bear an interesting relation to certain forms of disease; the runners in the so-called Marathon races developed counts of over 20,000; the polymorphonuclear cells increased 75 per cent. to 90 per cent.; the eosinophiles were absent, the lymphocytes diminished. These last observations were made in the hope that the runners would present hemic conditions which might throw some light on shock, since their profound depression seemed to simulate this condition, but such was not the case.

Effect on the Blood of Ether Used as an Anesthetic.—D. J. Chalmers Da Costa of Philadelphia said that no possible exception could be taken to his conclusions because of the care he had used in the preparation of the patients who had furnished the data for this report. By purgation and diaphoresis he had approximated them to the condition of the average operation case. Ether increases the number of the erythrocytes, diminishes the hemoglobin and reduces the color index. The hemolytic function is increased. He feels operation to be contra-indicated below 40 per cent. of hemoglobin, unless life be imperiled by the delay. In the presence of any anemia the routine purgation should be avoided or made as light as possible.

Examination of the Blood in Relation to Surgery of Scientific Value, but too Often of No Practical Value.—Dr. John B. Deaver of Philadelphia, with characteristic energy, affirmed that blood-counts, hematocrits, and so on, had taken altogether too prominent a place in surgery and were displacing bedside observations. He considered it absurd that any degree of anemia should stand in the way of a needed operation and said that he had never found any danger arising from anesthetizing and operating upon profoundly anemic patients.

In the discussion of these papers Dr. B. F. Curtis of New York said he was at a loss to interpret the reports from Boston. In his service at St. Luke's Hospital a great number of counts had been made with a view to establishing the

degree of leucocytosis which exists during ether anesthetization and he had considered it definitely proven that the count is always high irrespective of the patient's condition or the character of the operation. Intraspinal anesthesia yields a progressive increase in from one to five hours. He has considered post-operative leucocytosis so fixed a factor as to believe it seriously interferes with any prognosis of wound infection which might otherwise be gained through the hemic count.

(To be Continued)

ASSOCIATION OF AMERICAN PHYSICIANS.

Sixteenth Annual Meeting, Held at Washington, D. C., April 30 and May 1 and 2, 1901.

(Concluded from Page 723.)

Second Day—May 1st.

The nominees of the first day were all elected.

Clinical Features of Bubonic Plague.—Dr. L. F. Barker of Chicago gave a résumé of the clinical features observed by him in the plague cases at San Francisco. The disease is primarily a septicemia and may show a general sepsis without any local lesions; in the more resistant cases there may be only a local reaction and no marked general reaction. The San Francisco cases were not peculiar; they were identical with cases seen in other epidemics, resembling notably those observed in the beginning of a general epidemic. The type is a "sneaking" type, as was reported in the Bombay and Hong-kong epidemics before the great outbreak in those places. Thus far, in San Francisco few rats have been found to have the disease. While only 31 cases have been reported from San Francisco it is highly probable than more than this number have been attacked. Certain minor differences in age at onset and in the matter of sex were observed, but these were due purely to local conditions.

Type of Disease.—In San Francisco the type of the disease thus far has been truly bubonic, one case of primary septicemia and one of pulmonary invasion alone being reported. Should the disease become more prevalent other types will probably appear, but this is not now probable in view of the arrangement for sanitary control now provided.

Clinical Features.—The disease is usually ushered in by a chill and a rapid rise in temperature which may intermit and become irregular. Anorexia, nausea and vomiting, succeeded by delirium and coma are the symptoms in the acute severe cases. Within twenty-four hours a bubo appears and, the disease progressing, the patient may die on the fourth to sixth day. If the patient lives more than six days recovery is likely to occur. In those that persist for a number of weeks suppuration of the buboes occurs. The bubo affection is different from a simple lymphatic infection. It becomes very large, varying in size from a hen's egg to that of a man's fist; sometimes at first the gland itself may be palpated, but the rapid increase, not of a single lymph-node, but of the entire glandular structures soon makes a swelling markedly different from anything else. There develops a rapid and marked edema which has a peculiar elastic quality and the whole swelling shows signs of hemorrhagic infiltration. The attitude of the patient is often pathognomonic. A position which relaxes the tissues about the swollen gland is adopted; the patient usually being drawn up, the knees lying close to the chest, especially if the groin is involved. This is the favorite site, the cervical is next. No cases of axillary bubo were observed in the San Francisco cases. Cervical buboes are often associated with enlarged tonsils. Dr. Barker made a distinction between primary buboes and secondary ones. He also spoke of the pulmonic type, the septicemic type, *pestis siderans* and the walking cases, *pestis minor*. These latter were important cases, as they were very common at the beginning and end of an epidemic, and were of particular importance when the problem of control was under consideration. The question of so-called *climatic buboes* was of importance as it was claimed by many that the Chinese suffered from such an affection. Dr. Baker thought it wise to consider these plague cases until they were proved not to be so.

Prophylaxis.—The diagnosis of the first case was all important and in order to make such a diagnosis a dead patient was as useful, if not more so than a live one. A bacterial examination is the prime requisite. The diagnosis, he thought, was an extremely simple one for a trained bacteriologist who had had some clinical experience with the plague.

Differential Diagnosis.—The most important diseases to exclude are malaria, where a research for the parasite suffices, although mixed cases do occur; in the early stages of typhoid it is very difficult to make the diagnosis; in relapsing fever the *spirillum* is sufficient; venereal buboes, not difficult, as they do not have the characteristic edema, hemorrhage nor great infiltration; anthrax, bacterial diagnosis suffices. In Mongolians, he thought it wise to consider every case of fever as plague until proven otherwise and that every cadaver should be examined by a trained bacteriologist. Finally, with reference to treatment, the Roux-Yersin serum should be used.

Bacteriology of Plague.—Dr. F. G. Novy of Ann Arbor said, with reference to the bacterial diagnosis, that frequently the bacteria could not be obtained from the living patient. A hypodermic might be plunged into a bubo and the fluid obtained examined, but this did not always give positive results. Direct examination of the blood more often gave negative results, but cultural experiments were usually positive. In the pulmonary form the diagnosis

was very simple as the bacillus was found in the sputum in large quantities. It might also be found in the urine and in splenic pulp. Animal experimentations were necessary and final as most animals, notably the rat, gave positive evidences of the disease within a very short time. The typical plague bacillus is a short, stout rod, occurring singly and showing a peculiar bipolar staining, when fresh; old and senile specimens showed many involution forms. Dr. Novy described in detail the case of accidental infection of one of the laboratory workers at Ann Arbor occasioned by infection from one of the organisms obtained from the San Francisco expedition. The case was of the pulmonary type and recovered after free use of the Roux-Yersin serum.

Pathology of Bubonic Plague.—Dr. Simon Flexner of Philadelphia described in detail the characteristic lesions observed in these same cases. He though that the infection was largely a direct one and was spread in the body mainly through the lymphatics. He knew of no pathological condition which gave lesions which resembled those of the plague, hence a diagnosis of this disease might be made by a pathological examination alone. The glandular enlargement in the lymph-glands was due to a cell proliferation in the lymph-sinuses. The hemorrhage was excessive and characteristic; the edema was very prominent and was not confined to the lymphatic structures alone, but spread into the muscular tissues. The enormous growth of bacteria was marked; the organisms being numerous enough at times to cause thrombi in the lymph-sinuses, thereby causing obstruction to the flow of the lymphatics. This in part is responsible for the necrosis so frequently found. The pneumonia is usually of a lobular type, although by the merging of the lobules a pseudolobar pneumonia might result. Enlarged spleen, from vascular engorgement and an acute splenitis, is usually present. The bacteria may be thrown off from the skin, from suppurating buboes, from the sputum, from the buccal secretions, from the urine and from the feces. These excreta, therefore, should be disinfected.

In the discussion Surgeon-General Sternberg spoke of the debt that this country owed to the development of the study of bacteriology, inasmuch as had this disease occurred twenty years ago, it would in all probability have swept over the entire country.

Drs. Vaughan and Dock of Ann Arbor contributed some interesting details regarding the accidental case of laboratory plague already alluded to. Dr. Dock said that the Roux-Yersin serum probably saved the patient's life, as pulmonic-plague was usually fatal in every case.

Yellow Fever.—Drs. Walter Reed and James Carroll, U. S. A., reported some further details concerning the development of yellow fever. It had seemed to them that at this time it was more important to determine the precise mode of communication of the disease than to search for the specific organism, and they brought forward additional evidence in favor of the mosquito theory of conveyance. They made conclusive experiments bearing on three suspected modes of contagions: (1) By means of contaminated mosquitoes, *Culex fasciatus;* (2) by means of inoculations of blood, and, (3) by exposure to intimate contact with clothing, dejecta, etc. In some further experiments they proved that the method of contagion by blood inoculations was positive, as was also that by the mosquito, but that simple contact with fomites was negative in every case.

Incubation Period.—In blood inoculations, as well as by mosquito bites, the period of incubation averaged between three and four days. It was interesting to note that mosquitoes infected by biting yellow-fever patients were capable of transmitting the disease as late as seventy-one days after their infection.

Dr. Sternberg thought that the demonstrations of Drs. Reed and Carroll had now solved the problem of the contagion of yellow fever and had cleared up many of the apparent contradictions concerning its etiology.

Dr. W. H. Welch commented on the fact that the real heroes of the Spanish-American war were the United States soldiers who had volunteered to run the risks of being inoculated with yellow fever. None of them had died yet the honor was theirs.

Malarial Nephritis.—Dr. James Ewing of New York reported an interesting case of hemorrhagic nephritis due to the accumulation of enormous masses of the estivo-autumnal type of malarial parasite in the kidney. Renal disease is often due to toxic products derived from these parasites, but in this instance the cause was held to be a mechanical one. These masses of infected red cells formed thrombi which produced renal infarcts which in turn determined the degeneration of the cortical tubules. He said that three types of malarial nephritis might be distinguished: (1) An acute degeneration due to the development of toxic substances; (2) an acute degeneration due to focal necrosis in the hemoglobinuric type of malaria, and (3) a degeneration due to the development of masses of parasites which by mechanical means alone produced thrombi and renal infarcts.

Septic Infection from Stomach and Intestines.—Dr. Walter B. James said that septic infection through the gastric and duodenal mucosa was considered rare, but that of late years he had come to believe it more common than was usually supposed. The bacterial flora of the stomach and duodenum was very extensive and many researches had shown that numerous organisms survived the ordinary digestive processes. It was not then improbable

that if a solution of continuity of the gastric or duodenal mucosa was present that septic infection might take place thereby. He reported several cases showing mild and severe septicemia in which erosions of these mucous membranes, adenoma, ulcer, etc., were the only indications *postmortem* of the possibility of accounting for the conditions. In discussing the subject of gastric ulcer he said that over 50 per cent. of his cases in the Presbyterian Hospital had hectic fever, probably due to absorption through the eroded mucous membrane.

Streptothrical Infections.—Dr. J. H. Musser of Philadelphia reported two cases; one an abscess of the brain and another a bronchitis and bronchopneumonia in which organisms closely resembling *streptothrix* had been found. One of the cases might be considered as one of tuberculosis, with the peculiar type of branched bacillus tuberculosis.

Chemistry of the Tubercle Bacillus.—Drs. E. L. Trudeau and P. A. Levene of Saranac Lake presented specimens of bodies isolated from the tubercle bacillus. These were (1) a coloring body, reddish in general tint and fluorescent; (2) wax-like body, probably present in a proportion of about 30 per cent. in the organism; (3) cellulose body resembling somewhat the peculiar fungus cellulose, reacting like chitin of insects elytra, lobster shell, etc.; (4) three nucleoproteids, one of which produced almost pure nucleic acid, and (5) glycogen.

Dr. Abbott commented on the fact that the mucinoid substances developed by *bacillus pyocyaneus* showed reactions closely resembling mucin and cellulose.

Dr. Vaughan described an enormous incubator devised by him to cultivate large quantities of bacteria in order to further their chemical study. This culture chamber had a growing surface of 20 square feet.

Urine as a Culture Medium.—Dr. W. H. Park of New York presented a paper bearing on the practical question of the urine as a medium for the cultivation of bacteria. He showed that the acidity of the normal healthy urine had a wide amplitude of variation and that within the limits of such acidity, the growth of most pathogenic bacteria was diminished or checked. Thus, within the limits of the normal acidity, the gonococcus could not be made to grow and that acid urines were not favorable to the growth of the colon and typhoid bacilli, nor to the proteus nor staphylococcus. He had observed that in some urines no bacteria would grow. The practical point brought out was that an increase in the acidity was inimical to the growth of most of the pathogenic organisms and that by an increase in the acidity of the urine an efficient means could be found to prevent infection. In this manner cystitis, pyelitis and pyelonephritis might be avoided.

Orchitis and Typhoid Fever.—Dr. F. P. Kinnicutt of New York spoke of this comparatively rare complication of typhoid fever. In an analysis of some 800 cases of typhoid treated at the Presbyterian Hospital he had noted the complication in but two instances. In one case the gland suppurated and the *bacillus typhosus* was found in the pus. In cases occurring some weeks after the recovery of the patient, it is not improbable that some other cause might be found. He made a résumé of the available literature and showed that in many cases the typhoid organism had been found either in the serum of the gland or in suppurative foci and it therefore seemed proved that the typhoid organism bore a direct relation to the orchitis. It is probable that the organisms reach the vas deferens by means of the blood channel. Thrombi occur, phlebitis develops and the orchitis thus has its origin. He concluded that orchitis was a rare complication of typhoid fever; it occurs late in the disease or during convalescence; it may be unilateral or bilateral and goes on to resolution, suppuration occurring in but 25 per cent.; local necrosis, however, of a portion of the testis is not uncommon, or the entire testicle may be destroyed; atrophy of the testicle may perhaps develop; there is little constitutional disturbance and death by reason of the accident is thus far unknown.

Treatment of Cancer by the Roentgen Rays.—Dr. F. H. Williams of Boston said that at the present time it was premature to draw any conclusions regarding the ultimate value that the X-ray might be found to have in the treatment of cancer. The present outlook, however, was very hopeful. In certain cases of flat epithelioma of the face, which were amenable to treatment by simple caustics, the burning action of the X-rays filled a similar office, and here could be considered merely as a caustic. In other cases, and these were those for which much is expected, the caustic action does not account for the benefit obtained. In a number of cases of flat epithelioma of the face, 11 being reported, the results were excellent. One case of epidermal cancer of the lips and a large flat epithelioma of the hand were reported and photographs shown, evidencing the value of the treatment.

Advantages and Disadvantages.—The safety of the method was spoken of. There was not pain, nor delay in the beginning of treatment, as is so frequently necessary in raising the tone of the patient to stand an operative shock; no burns are produced, the cosmetic effects are excellent; sometimes improvement once begun goes on to cure without continuous treatment; the patients can attend regularly to their work. Some of the disadvantages were the necessity of great care in the prevention of burns, the expense of the apparatus and the long-continued course of treatment necessary.

Osteitis Deformans.—Drs. F. A. Packard and J. Dutton Steele of Philadelphia reported a case of this rare disease. Comment was made of the fact that diagnosis during life was very difficult and that in view of the great lack of criteria by which the general subject of bony lesions was to be judged, they offered no theories regarding the probable nature of the affection.

Arthritis Deformans.—Dr. William Osler of Baltimore spoke of the obscurity concerning the etiology of this affection. Is it nervous? Does it belong to the peculiar unknown groups of para-bacillary diseases. Are there several distinct types of the affection? He spoke of three fairly well-marked clinical manifestations. One occurring in young children with enlarged spleens and involved lymp-nodes; another occurring in adults, with atrophic changes, and a third, also in adults, usually past middle life, with the development of ringbone, osteophytes, many of which are developed with great suddenness. At times the disease shows curious localizations, sometimes involving several joints, again only a few, symmetrically disposed joints. An acute onset, resembling rheumatism is not infrequent.

Spinal Column Cases.—He alluded to the interest manifested of late years in this type of cases, especially taken by neurologists. Two forms were considered in detail. In the Von Bechterew type there was great rigidity of the spinal column, with marked kyphosis, muscular atrophy. In addition there was a marked hereditary tendency, usually a history of injury, but most important there were symptoms, chiefly pain and other sensory disturbances, which pointed to an implication of the nerve-roots, just within the cord or the spinal processes. In a second type the Marie-Strümpell variety, there was the same spinal rigidity and kyphosis, and in addition a marked tendency on the part of the larger joints to become ankylosed. There are no root symptoms in this type. Dr. Osler was inclined to the belief that it was not necessary to suppose these to be different affections and due to disease of the nervous system; it was wiser not to dissociate them and to regard them essentially as joint lesions and to account for the root symptoms, in Von Bechterew's cases especially, on purely mechanical grounds.

Dr. F. Stockton of Buffalo and Dr. Lamb of Washington exhibited some skeletons showing characteristic lesions of this affection.

In the discussion Dr. B. Sachs of New York said that he coincided, in the main, with what Dr. Osler had said. He did not regard Von Bechterew as correct in his interpretation of the cause of the root symptoms.

Dr. Cabot said that acute destruction as seen in the atrophic cases and chronic production as seen in the larger number of cases, should not be considered as different stages of the same pathological process; they were, in all probability different entities. He called attention to the great benefit that might be secured to such patients by the use of mechanical support. Many intractable cases, usually termed a mixture of lumbago and sciatica, are often cured by appropriate mechanical support.

Tropho-Neuroses and Vascular Diseases of the Extremities.—Dr. B. Sachs of New York said that in studying a case of erythromelalgia his attention had been called to the marked degeneration, with thickening, arteritis obliterans, of the blood-vessels of the affected area. This had led him to the proposition that perhaps many of the so-called tropho-neuroses might not be nervous in their origin, either as due to central nerve changes or as nerve end neuritides, but were possibly due to arterial changes. It was of much importance that a proper appreciation of the general condition of the blood-vessels should be kept in mind in the study of all cases supposed to belong to the class of tropho-neuroses. An investigation of the condition of the arteries of the lower extremities is of much value and is frequently overlooked.

Subcortical Glioma.—Dr. J. Stewart of Montreal gave a history in detail of a case which in its early phases presented attacks of disarthyria and deaf mutism for periods of one-half hour or so. Headaches, twitching of the muscles of the face developed and at times numbness in the face and arms. Failing sight was also a symptom. With reference to the disarthyria the labials were first affected. The symptoms developed progressively until complete anarthyria was present. A slight grade of dysgraphia developed. There was no aphasia. It was diagnosed that the lesion was subcortical and on operation a normal cortex was found; beneath the lower part of the ascending frontal convolution a dense mass could be palpated and a firm encapsulated tumor, 1 x ¾ inch, was enucleated. This proved to be a glioma. The patient ultimately recovered.

Jacksonian Epilepsy.—Dr. James J. Putnam of Boston said that within recent years it had become for him a distinct query whether operation for the relief or cure of Jacksonian epilepsy was advisable. He asked if, in the first place, the operation was of any use? If cortical excision alone was sufficient, and, finally, how could the symptoms of epilepsy be explained by any theory of cortical action? In reply to the first question his answer was, yes, as the number of cases which the operation had benefited was too great to gainsay. It was a question, however, whether cortical excision alone was sufficient. In a number of instances he had observed that the simple opening of the skull or with excision of the dura had been sufficient to relieve the epileptic attacks, for a time at least. In such cases

suggestion thereby seemed the only applicable theory to apply. Dr. Putnam did not believe much in a cortical epileptic center.

In the discussion Dr. Sachs said that whereas a healthy conservatism had been manifest of late years with reference to this operation, nevertheless it was advisable to operate early in such cases. If the time was well chosen better results might be obtained.

Family Periodic Paralysis.—Drs. J. K. Mitchell, S. Flexner and D. L. Edsall of Philadephia reported two cases of this affection in detail with a series of chemical and blood investigations made with a view to arrive at clearer ideas regarding its etiology. Animal experiments proved negative. No products toxic to guinea-pigs or rabbits were obtained either in the blood or in the urine. During an attack there was an increased alkalinity of the blood. Search for acetone, di-acetic acid, etc., was negative. The investigation of the amount of kreatin and kreatinin seemed to offer some light, as an increase in these products usually preceded the attacks. The disturbed metabolism took place largely in the affected muscles themselves. Citrate of potash had proven of some value in the therapy.

Heredity of Appendicitis.—Dr. F. Forscheimer of Cincinnati showed charts of three families in which a distinct family history of appendicitis could be shown for several generations. In many of the cases an attendant neurotic history was also manifest.

Third Day—May 2d.

Diverticulum of the Esophagus.—Dr. F. Pfaff of Boston gave a series of observations concerning the process of digestion as a result of the investigation of the contents of an esophageal diverticulum. The patient learned to feed himself by means of the stomach-tube, but regurgitated all solid food taken by the mouth.

Action of Ptyalin on Digestion.—In the diverticulum it was shown that a certain percentage of starch digestion could go on. There was no pepsin nor HCl in the diverticulum. Within the stomach an entire absence of ptyalin had no adverse results on the digestive process. Its action could be dispensed with. Lactic acid could be found in the diverticulum if there was bacterial action, but in the absence of such this acid did not develop. Absorption from the walls of the diverticulum was *nil*. The amount of modification of the epithelium should be considered a factor nevertheless.

Early Recognition of Tuberculosis.—Dr. E. L. Trudeau of Saranac Lake said that much of the lack of success in the sanatorium treatment of tuberculosis was due to the fact that the patients were sent there too late in the disease. It was very plain to him that in the distinctly incipient stages, the disease was curable by the sanatorium method, but that his experience bore out that of others working in similar fields, that the great majority of the cases came when advanced inroads had been made by the tuberculous process. The most important factor, he thought, was that of early diagnosis, and much of the time spent on useless methods, such as counting bacteria, might better be spent in perfecting one's self in the art of diagnosis, especially with the view to the discovery of the initial onset. In veiled cases he advocated the use of the tuberculin reaction.

Burns.—Drs. J. G. Adami and J. McCrae of Montreal read a paper on this subject. They found that the pathological changes, especially in the lymphatics, resembled very closely those found after death by the bacterial toxins, diphtheria, for instance, and they were led to consider that the cause of death in extensive burns might be due to some form of toxemia, possibly hemic in its origin. This toxemia is probably chemical in its nature and affects other organs of the body, notably the kidneys, in which an acute degenerative nephritis is set up.

Hemolysis.—Dr. S. J. Meltzer of New York read a paper on this subject. He discussed in full the subjects of immunity and agglutination, from the analogous standpoint of hemolysis. It has been shown that the effects of the blood of an animal of one species had a marked effect on the red corpuscles of another species. This was first learned when animal blood transfusions were practised. In practise this phenomenon has been widely studied and shows many analogies to the action of sera on bacterial bodies. There are certain natural poisons for red blood-cells; they contain hemolytic substances; thus, eel's serum is very markedly destructive to the red cells of the rabbit. By repeated vaccination, however, the rabbit's blood may acquire antitoxic powers which will ultimately protect the red cells from the hemolysins of the eel's serum. Dr. Meltzer's studies were principally along the line of introducing heterologous blood sera into the peritoneal cavity of other animals, whereby the antitoxic properties were developed. The subject is a new one and requires many more observations to permit generalizations.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held April 8, 1901.

J. Blake White, M.D., Chairman for the Borough of Manhattan, Presiding.

Food as a Factor in the Causation of Disease.—Dr. Elmer Lee read a paper on this subject. The science of living, he said, begins at the mouth. As a man eats and digests his food, so is he. Disease is latent in every man,

and at all times. Food is both the saving and the undoing of health. Food, rightly used, means health and strength. Neglect to feed the body safely is the starting-point in pathology. The universality of sickness, suffering and premature death requires a universal cause for their explanation. The habit of letting into the system unprepared and unsafe nutriment is the only admissible solution. Theories have long been put out to explain the riddle, but have ever remained theories. In the extreme urgency to satisfy the demand for an answer to the question, plausible hypotheses have grown up. The germ theory is the one most prominent at this time, but it is incomplete and unsatisfactory, for it cannot account for the germ itself.

There is one health, and that condition which is not health is disease. Any departure from perfect health and economy of vital action is a first stage of disease. Every variation from the normal state is a degree. Sickness is composed of many degrees. The words "slight," "serious," "dangerous" and "fatal" are terms representing different states or degrees of disease. But in each instance disease is a backward process, while health is progressive. Inaction and retarded action within the body are the beginnings of disease from the misuse of food. As food enters into the substance of man, so is it his health or the opposite. All systems of medicine amount to nothing unless founded on what is carried within the human body as essential nutriment to its growth and life. The right uses of food build for health and vigor and preclude disease. Each physician should apply the test of sound and continuous health to himself as the measure of his scientific knowledge of human vital action. Sound and continuous health is the sequence of habitual living by knowledge and not by chance.

Statements of the Paper Too Sweeping.—Dr. Ransford E. Van Gieson thought that all must acknowledge that the improper selection and preparation of food and imperfect mastication are undoubtedly responsible for a large amount of ill health. Man is more or less an animal, but his instincts do not always guide him correctly, as in the case of the lower animals. Doubtless the broad ground taken by Dr. Lee is measurably true, and it is a matter of observation that the physician who is most successful is he who takes the greatest pains to instruct his patients in regard to their diet and the proper manner of taking it. But, at the same time, Dr. Van Gieson said, he was not prepared to accept in its totality the theory as to the universal causation of disease set forth in the paper. He would especially take exception as regards the etiology of epidemic disease. Like most medical practitioners, as they grew older, he had come to entertain doubts as to the universality of germ pathogeny, but still he could not but believe that there are certain forms of epidemic disease the origin of which is explainable on no other hypothesis. Take, for instance, influenza, which sweeps rapidly over a community and strikes down not only the weak, but the strong and those who are in perfect health.

Necessity of Complete Mastication.—Within the past two weeks he had found it necessary no less than fifty times to urge the advice, *eat slowly*, in cases of various forms of indigestion presenting themselves in his practice. If such patients told him that they were obliged to eat their meals hurriedly he instructed them that it was much better to go without eating at all until they could get time to eat properly. It was unfortunately true that most of us were apt, in our busy practice, to lose sight of the elementary truth regarding this most important subject.

Every Physician Should Be a Good Cook.—Every practitioner should know practically how to cook. Even the best trained nurses were often woefully ignorant on this matter, and the medical attendant should always be ready to give exact instructions as to the proper preparation of diet, and, if need be, to prepare it himself.

Various Forms of Disease Caused by Special Kinds of Food.—Dr. Edward Quintard said that one good reason why the teachings of Hippocrates still survived and were still held in such high esteem was because they were characterized by such strong common sense. On the present occasion he would not attempt any theorizing, but would briefly relate a few instances coming under his personal observation in which special varieties of disease were produced by particular articles of diet. Having spoken of the eczematous-like eruption caused by oatmeal, he said that he had met with three cases in which the eating of salted almonds resulted in the production of peculiar little ulcers of the tongue. He had frequently observed that the free use of sweets and pastry gave rise to a peculiar form of gastritis accompanied by hyperacidity. In subjects with a tendency to affections of the mucous membranes highly-seasoned foods were also very apt to produce gastritis. From cases he had observed he was inclined to the opinion that in chlorotic girls, much given to the use of sweets and suffering from hyperacidity, such food is sometimes the cause of gastric ulcer. There is a peculiar form of diarrhea, almost dysenteric in character and coming on almost immediately after meals, which is due to an inordinate amount of fluid taken with the meals. This had the effect of diluting the gastric juice to such an extent that it could not properly perform its function, and increased peristalsis was caused by the irritation thus set up in the intestine.

Bacteriology Not Ignored.—Dr. C. N. B. Cammac said that Dr. Lee's ideas were far from being out of accord with the results of

bacteriological research. It was because of a loss of nutrition in some part of the body that the disease germs were enabled to get a foothold. Thus, pernicious anemia was caused by a gradual failure of resistance on the part of the digestive tract to the onset of microorganisms having a destructive action upon the blood.

Not Safe to Generalize Too Much.—Dr. A. Rose thought there was a danger in generalizing too much. He had known of patients who, under a carefully-regulated diet prescribed by stomach specialists, had continued to suffer greatly, but who, when allowed to eat everything they wanted to, immediately got well. We should not forget that what is satisfactory in the case of one individual may be dangerous to another. Gerhardt had pointed out that many of the late hemorrhages in typhoid fever were due, not to typhoid ulcerations in the intestine, but to a form of scurvy resulting from an exclusive milk diet. He therefore advised that typhoid patients should be given more or less vegetable food, such as spinach, watercress, and the like.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held April 8, 1901.

The President, L. Hektoen, M.D., in the Chair.

Varicose Veins of the Right Upper Extremity in a Child.—Dr. Bertha E. Bush reported this case, placing on record a developmental varix, in a young child, the process affecting the anterior superficial veins of the entire right hand, arm and shoulder. Numerous saccular dilatations occur just beneath the skin, those at the inner end of the clavicle and in the palm of the hand being the most conspicuous. Skiagraphs show deformity of the right metacarpal bones, and generally diminished growth of the arm and hand. There is no pulsation nor edema, and no history of hemorrhage. Noteworthy points in the case are: (1) The congenital origin; (2) the region involved; (3) the obscure etiology, and (4) the scarcity of literature.

Blastomycetic (Oidiomycetic) Dermatitis.—Dr. H. T. Ricketts presented a consideration of this condition, with demonstrations. Through the courtesies from Professors Hyde, Montgomery and Hektoen, he had studied the pathological and mycological features of ten new cases of blastomycetic (oidiomycetic) dermatitis observed during the last eighteen months, mostly in the clinic of Professors Hyde and Montgomery. The work was done in the Pathological Laboratory of Rush Medical College. There is a clinical history in all cases; the process beginning as a pustule, which becomes a larger ulcer, the surface later being covered with coarse papillæ bathed in pus. A reddish areola containing miliary abscesses surrounds the verrucose tissue; the center of the lesion cicatrizes as the periphery extends.

The histological features are uniform; carcinomatoid proliferation, and leucocytic infiltration of the epithelium, intra-epithelial abscesses, premature and abnormal cornification, peculiar retrogressive epithelial changes and epithelial giant cells, and in the corium, dense leucocytic and plasma-cell infiltration, fixed tissue proliferation, subcutaneous abscesses, giant cells and tubercles, resembling those of tuberculosis, but being less typical in the inter-relationship of cells and showing less advanced regressive changes. Plasma-cells seek the periphery of the process. Apparently there is an eosinophilous type of the disease, which, in the cases studied, is associated with a mold-fungus form of the parasite, and very large papillæ. Russel's fuchsin bodies are found in plasma-cells and intercellular spaces. There is a close relationship between plasma-cells and the formation of a peripheral protective zone of fibrous tissue. They do not appear to become fibroblasts, but to undergo a gradual disintegration as provender for forming fibrous tissue. Mast-cells exist in large numbers, and are classified as (1) leucocytic; (2) connective tissue cell type; (3) those possessing halos; and, (4) the plasma-mast-cell type. In the tissue the organisms are found singly, in budding pairs and in groups, in intra-epithelial and subcutaneous abscesses, free between healthy rete cells, in giant cells, and in the granulation tissue of the corium.

Organism Cultivated.—From seven cases the organisms have been cultivated. They fall into three groups: (1) the yeast-like, resembling those of Hektoen, Hessler, Busse and Curtis; (2) the oidium-like; (3) the mold-fungus type, resembling the organism isolated by Ophulis and Moffit from the protozoic (?) disease. Study shows that all these have common generic properties, and are separated only by specific characteristics which are more or less variable. In accordance with pre-existing nomenclature they all belong to the genus oidium. "Blastomyces" is considered not sufficiently inclusive. Pure cultures inoculated into animals produce local abscesses, septicemia, or if injected into veins, mycotic nodules and consolidation in the lungs. The various methods of proliferation in cultures are, germination, lateral conidia, terminal spore-groups, abjunction of mycelial segments, aerial conidium-bearing hyphæ (in the mold-fungus), and questionable endogenous spore-formation.

Of many inoculations of tissue from man into guinea-pigs, none have resulted in tuberculosis. A study of Busse's case of "Sacchromycosis hominis," of the protozoic (?) disease of Wernicke, Gilchrist, Ophulis and Moffit, and others, and of Blastomycetic dermatitis, together with the fungi concerned in

all, affords convincing evidence that the three are closely related processes, caused by similar organisms; the protozoic (?) disease and Saccharomycosis hominis (Busse) are examples of the generalized infection, while Blastomycetic dermatitis (Gilchrist) is a local manifestation of the disease.

The term *Oidiomycosis* is suggested as a name for the combined manifestations.

Dr. Maxmillian Herzog said that if so many varieties of organisms are found in cases of clinical blastomycetic dermatitis, they can not be a single disease which is due to a single cause.

Dr. Ricketts in closing said he did not insist on the use of the term oidiomycosis. He considered the protozoan diseases as due to an organism very closely related to the ones under consideration.

Infection by the Bacillus Aerogenes Capsulatus.—Dr L. M. Loeb reported two cases of this infection. (1) A compound fracture of both bones of the forearm was followed by emphysema of the whole extremity in two days. Recovery took place uninterruptedly after shoulder amputation. (2) An abrasion of the outer side of the knee was followed in one day by phlegmonous emphysema of the entire leg and by constitutional symptoms of profound intoxication. Fifteen to twenty short incisions were made and drainage of bichloride dressings employed. In ten days gas bacilli and emphysema were gone and recovery interrupted only by a suppuration of the knee joint took place. This case again brings up to consideration the more conservative methods of treatment.

Dr. L. F. Barker spoke on the circumstances of the discovery of the organism. He urged early recognition of the disease and treatment.

Dr. H. Gideon Wells mentioned a case in which the emphysema was first noticed in the subcutaneous tissue of the left shoulder, extending some distance in the course of a few days. Because of the finding of pulmonary tuberculosis, it was suspected the emphysema was due to a tuberculous abscess connected with the chest wall which had ruptured. At autopsy this was found to be not the case, but due to the bacillus aerogenes capsulatus.

BOOK REVIEWS.

A Text-Book of Pharmacology and Therapeutics, or the action of Drugs in Health and Disease. By Arthur R. Cushney, M.A., M.D., Professor of Materia Medica in the University of Michigan. Second Edition. Lea Brothers & Co., Philadelphia and New York.

To cut loose from established precedent and to weed out superfluities and ruthlessly annihilate antique dogmas take a large amount of courage even in a text-book writer. It is because Dr. Cushney has had the courage of his convictions that, from certain standpoints, he has given us perhaps the best text-book on pharmacology that the English-speaking student can obtain.

It is for its distinctly modern tone that this text-book is to be praised. Recent workers in pharmo-dynamics have established many truths which are largely antagonistic to old-fashioned dicta and it is refreshing to read a work, which, while it does breathe an atmosphere of therapeutic pessimism, does so in no critical nihilistic sense, but in the desire to know truths that may serve as rational grounds for treatment. Hence he rejects many of the old teachings regarding the uses of alkalies and acids, the peculiar effects of bitters and many other routine procedures born of empiricism.

The workers in the field of theoretical chemistry, Nernst, Ostwald and others, have opened up a new vista in pharmaco-dynamics and Dr. Cushney has seen fit, and wisely, to incorporate in this work the teachings in this new field which offers much promise in future therapeutics. While much of it is as yet vague, and expressed therefore with great difficulty, in which regard our author has often not helped matters, yet the time is not far distant when the student of drug activities must thoroughly comprehend the theories of ionization and their significance in the giving of drugs for remedial purposes.

We would desire to see in Dr. Cushney's work a more intimate commingling of the results of the laboratory to bedside work, but if this is impossible, we believe that the practitioner who thoroughly understands drug-action, as outlined in a book of this kind, is infinitely better prepared to treat any condition than one whose brain is a storehouse of prescriptions.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

A System of Practical Therapeutics. Edited by Dr. H. A. Hare. Second Edition. Vol. II. Fevers, Diseases of Respiratory, Circulatory and Digestive Systems, Diseases of Kidneys, Nervous System and the Skin. 8vo, 926 pages. Lea Brothers & Co., Philadelphia and New York.

The International Medical Annual. 1901. Nineteenth year. 8vo, 682 pages. E. B. Treat & Co., New York and Chicago.

First Aid to the Injured and Ambulance Drill. By S. H. Drinkwater. 12mo, 104 pages. Illustrated. Aldine House, London.

A Laboratory Guide in Elementary Bacteriology. By Dr. W. D. Frost. 8vo, 205 pages. Published by the Author, Madison, Wisconsin. $1.60.

Twenty-fifth Annual Report of the Managers and Officers of the New Jersey State Hospital at Morris Plains. For the year ending Oct. 31, 1900.

Seventh Annual Report of the Board of Managers of the Craig Colony for Epileptics.

Nursing Ethics for Hospital and Private Use. By Isabel Hampton Robb. Demi 8vo, 275 pages. J. B. Savage, Cleveland, Ohio. $2.00.

ORIGINAL ARTICLES.

ON THE MODERN TREATMENT OF ACUTE GONORRHEA.[1]

BY GEORGE KNOWLES SWINBURNE, M.D.,
OF NEW YORK;
SURGEON TO GOOD SAMARITAN HOSPITAL.

A PHYSICIAN, whose scientific attainments I have always held in the greatest respect, once said to me, "I have studied and treated gonorrhea for fifteen years and I feel to-day that I know less about that disease that I thought I did several years ago." It is in that same spirit that I stand before you to-night, and if I seem to you to be too strong an advocate in the use of certain remedies, I wish to say at the outset that I have seen cases which had been treated along these lines which were possessors of as inveterate conditions of urethral disease as any you will find among those treated by more conservative methods. Have some of those cases that must have wandered away from me to go to others been also found to be in such condition? I do not like to think so.

A man presented himself to the writer in the early part of the winter with a gonococcus-bearing discharge of more than two years' standing, the outcome of his first attack. It had been treated in the early stages by one of the ablest specialists and his assistants in a neighboring city. Frequent urethral irrigation with permanganate of potassium was the treatment. In due course of time he had a posterior urethritis followed by epididymitis, a length of time in bed, during which there was brief cessation of discharge. After he was up and about the discharge returned. More permanganate irrigations were used, which he said produced such pain that the strength of the solution had to be reduced to about 1-15,000 before it could be borne. He then visited another specialist, who changed the treatment, and in time there was apparently a complete cessation of discharge and elimination of the gonococci under careful use of protargol in varying strength. The patient then took a trip to Europe, during which time he paid no attention to himself, drank moderately of the wine of the country, but did notice that after indulgence in beer a rather uncomfortable moisture appeared each morning for a few days following. Several months after this he came to New York to settle in business and as time went on he found himself possessed of the constant morning drop and it was then that he came to consult the writer.

This same sequence of events can be duplicated by every method of treatment that has ever been tried or advocated—whether radical and local measures or conservative and internal medication have been used. I therefore hesitate to lay down any one method of treatment as the ideal one assuring success. There will always be a percentage of failures and those claiming the highest percentage of successes will only be looked upon as colossal distorters of the truth or as observers of an inferior order. The truth is that the treatment of this disorder is as much an art to be cultivated as is the treatment of disease in any other department of medicine or surgery.

You cannot take a set of human animals afflicted with the same disease, put them in at one end of a process of treatment, giving each the same dosage, same interval between each treatment and bring them all out of the other end cured. The time is too short to attempt to enumerate a few of the factors militating against success, such as powers of resistance of the patient, special virulence of the acquired germ, lapses in diet, attendance, etc., on the part of the patient; the physician not always alive to changes in the disease; not always keyed up to a keen sense of the patient's real condition; he may not do his work always with the same degree of skill. Why is the profession, why are we all, constantly trying new remedies which have recently come out, one after the other, with bewildering multiplicity? It is because all who are taking active part in treating this disease are alive to the many conditions to be filled and each new drug has something to recommend it, some improvement embodied in it. Some fill the conditions better than others, some disappoint utterly, theoretically ideal, practically worthless. These new silver salts, their object is to possess the greatest germicidal quality with the least irritating effect.

We are told by one set of observers, "Oh, yes, granted your remedies do this and that; you apparently eliminate the gonococci, but you only change them; they remain latent, but they are there, and your cases you call cured are capable sooner or later of infecting, or they will develop the signs of the sequelæ of gonorrhea." The answer to that is, give us the tests with which to prove the disease still present. As a matter of fact this is true in some instances, but because of this you must not say this is true in all instances. Extremists on the other side say, "Oh, yes, you treat your cases conservatively, but wait a few years till they marry and then see the devastation caused." True again in some instances, but surely not in all. To each I would say take a few lessons from your brother practitioner—he, if he has the experience, has something to teach you.

Every case is a law unto itself. I have seen

[1] Read before the New York Academy of Medicine, March 21, 1901.

cases which have been treated carefully by internal medication, suffer the extreme pains which uncomplicated cases can suffer, quickly take a turn for the better and rapidly recover when treated locally, and I have seen cases treated locally with the greatest care and with the newest remedies and the gonococcus thrive upon the treatment. Therefore, each case has to be studied by itself and treated as indications arise by the light of previous experience, and if during the course of the disease the case comes to a standstill (I am talking of the acute disease) we should look to make some change in treatment. It seems to me that the wider one's experience with different remedies, the quicker one can pick the one fitted for the particular case.

The microscope is our greatest aid in the treatment of gonorrhea. Without it we cannot intelligently treat this disease. The day has gone by when all urethral discharges are treated alike and empirically. Not only is it the chief factor today in making the diagnosis, but also in determining the course of the treatment, and in acute cases it should be used at every visit.

The diagnosis of an ordinary acute gonorrhea is generally easy; in no case should the microscopic examination of the secretion be omitted, no matter how sure one may be of his diagnosis. The gonococcus is a diplococcus. Each half is kidney-shaped with the straight sides facing each other, separated by a minute space so that a single pair has the appearance of the flat surface of a coffee bean. They are arranged in pairs, fours, eights, etc., and appear in groups. One marked peculiarity is their arrangement within the pus cells; they may also be seen outside and between the pus cells and on or within the epithelial cells. They are best seen with an oil immersion lens. An easy method of finding them is by means of the methylene blue stain. A saturated solution of the methylene blue in absolute alcohol should be kept as a stock solution. A few drops of this added to an ounce of distilled water, enough to cause a dark blue color, will serve to make many stainings. A good stain may be obtained by making a thin smear of the secretion on a glass slide, drying it carefully over the alcohol flame, then covering the smear with a few drops of the aqueous blue solution, and then after a half minute washing the slide with a little plain water, dry and place a drop of cedar oil directly on the stained surface and examine under the immersion lens without the use of a cover glass.

For ordinary office work this method is found to be very satisfactory and after one has become familiar with the appearance of the field containing intracellular diplococci a more elaborate method will be found to be of use in special cases only. There are many other stains which may be of use, but this is the simplest and most valuable, at least in acute cases.

The so-called Gram-Roux method of staining is, of course, more accurate and sometimes will be found to be an important help, but where it is used for greater accuracy of diagnosis it is often necessary also to employ the culture test. This method, however, is of great use, especially in examinations of discharges from chronic gonorrhea or in the later stage of the acute form. These methods depend upon the greater ease with which the gonococcus gives up to its stain as compared with other diplococci which resemble it.

In carrying out the method the most careful attention to detail is necessary. The smear is first stained for two minutes with some stain in aniline water. The aniline water should be comparative fresh and is made by shaking distilled water with aniline oil and then filtering; to the aniline water thus made, enough saturated alcoholic solution of the desired stain, as gentian violet, is added to give it a fairly deep tinge. The surplus of stain is removed with blotting paper, but the slide should not be washed. The Lugol's or Gram's solution is then added to the smear for the same length of time as the gentian violet stain and dried with blotting paper without washing. This solution consists of iodine one part, iodide of potassium two parts, water 300 parts. It is this stain which fixes the aniline stain in the other micro-organisms. Absolute alcohol is then employed to decolorize the smear until to the naked eye it appears colorless. The specimen may then be washed. The counter stain used is generally Bismarck brown prepared as follows: Bismarck brown, 3 parts; water, 70 parts; alcohol, 30 parts. The specimen is stained with this for about three minutes, then washed, dried and examined under the oil immersion lens.

I have observed a few anomalies in cases coming very early and where I made a mistake in diagnosis for that reason. These all occurred in men who had had previous attacks, coming on the first day of their noting an increase or rather starting up of a new discharge. A number of micro-organisms would be found and no appearance of the gonococcus and the case pronounced to be not a gonorrhea and no immediate treatment instituted. On seeing these cases at a later period, one coming on the following day and another at an interval of three of four days, the discharge having increased in amount, it was found to contain a pure culture of gonococci. The knowledge that such a phenomenon may occur should prevent us from arriving at too hasty a conclusion.

Another way in which the finding of the microscope may be misinterpreted is illustrated by a case seen on the first day of the discharge by one physician, who found gonococci present in the discharge and furnished the patient with a solution of protargol to use himself during the day. This caused increase of the discharge and considerable discomfort on the part of the patient, and on his return the following day he was seen by another physician, owing to the illness of the first, who found that in the rather profuse purulent discharge no micro-organisms of any kind were present. Having no knowledge of the previous finding, he at once pronounced the case as not a gonorrhea, but a discharge due to a chemical irritation and advised the discontinuance of

the treatment. The secretion quickly subsided and remained so for ten days, when it reappeared and at the same time was accompanied by symptoms of posterior urethritis, the patient having during that time indulged freely in alcoholics. A knowledge that oftentimes a single injection of protargol will cause a disappearance of the gonococci for twenty-four hours or even longer would have saved the second physician from making this mistake.

There is more than one way, then, to treat gonorrhea successfully in its acute stages, and methods which prove successful in the majority of cases in the hands of one man may prove disastrous when tried by another or attempted by the patient himself. Some general rules must be laid down as guides to follow and I propose to describe those methods which I rely upon for guidance.

In acute gonorrhea we have to deal with what is known as a self-limited disease, but which by reason of bad treatment or neglect or lack of constitutional vigor is capable of lasting indefinitely or setting up pathological lesions which will always leave their impress upon the organism. Though the disease may be self-limited in the sense that its most prominent symptom, a urethral discharge, definitely ceases, yet the etiological factor, the gonococcus, may remain indefinitely, thereby capable of infecting others unless means are taken to eradicate it; while in the absence of irritation the urethra will be immune in a sense to its own gonococci. In this condition it is, however, capable of receiving a fresh infection and undergoing a new typical attack. Under certain conditions, whether by the action of irritants or from overindulgence in either alcohol or coitus, a discharge may be set up in which these gonococci will be found in increasing numbers, but may quickly subside with only hygienic treatment though the contagious element still remains as before.

Some cases even when untreated or only indifferently treated will recover and the gonococcus will die out completely, but in many of these cases urethral lesions may be left behind which will form a focus for the infection of other pathogenic organisms which readily find their way into the anterior urethra.

The earlier the diagnosis of gonorrhea can be made and consequently treatment for its eradication be instituted, the quicker and more safely can the case be brought to a successful termination with less chance of accidental complications or the disease going on to a chronic process. Many physicians make the mistake of waiting in the presence of a slight urethral discharge for further development, instead of making an immediate microscopic examination to establish the diagnosis. Or the patient will try some remedies of his own or of a friend before presenting himself and valuable time is thus lost. Patients with their first attack are unsatisfactory often for another reason; they not only waste valuable time at the start, but often come with the idea that they are to be cured quickly, and at the first cessation of the discharge, stop coming, with the result that a fresh outbreak, indicating an infection deeper in the canal, springs up, which is far more difficult to eradicate than it would have been had they not ceased to attend, thus rendering their first visits absolutely useless.

All who have had any experience in the treatment of gonorrhea recognize that there is a vast difference between a case with its first attack and one which has had multiple attacks in their reaction under treatment. Nevertheless, in the treatment about to be described, when used at the earliest possible moment, there seems to be no difference in the reaction to treatment, unless it be that the average is rather better in those patients with their first attack. Though there may be difference of opinion as to the proper management of a case which has existed for several days, still in the light of past experience there is absolutely no doubt in my mind as to the desirability of instituting radical measures at once if the case has come early in the disease, and hours make a vast deal of difference at this time.

Hot irrigations have been found to be soothing to the inflamed urethral canal, but plain water is also irritating, therefore I have continued the use of permanganate, but in weaker solution than formerly. Undoubtedly other solutions may be found as good—perhaps a saline solution as given in a recent issue of the *Medical Record* in an excellent article by Dr. Woodruff. The heat undoubtedly has an effect on the gonococci in the deeper portion of the tissues. Irrigations have to be copious and frequent, but must be used by the physician himself. Beginning at 105° to 110° F. the heat can readily be carried up higher to 120° F. The test is the effect on the patients; it should be non-irritating.

Next, the germicide: in acute disease protargol in varying strength, from ½ per cent. to 2 per cent., held for ten minutes. As a beginning injection I now use a full urethral syringe, half fill it with a 2-per-cent. cocaine solution, and fill the remainder with 2-per-cent. protargol. At each successive visit the cocaine is diminished and protargol increased, until the full strength 2-per-cent. protargol is used, if it can be borne by the patient without undue irritation; but here again the strength is made according to its effect on the patient and the cocaine dropped entirely by the third or fourth visit.

The anterior urethra only is treated, as long as the anterior urethra only is affected. In cases seen early I try to have the treatment given for three or four days if necessary, twice a day. Sometimes only the first day is it necessary to come twice; sometimes if the patient can stand it and is willing to come twice a day for a longer period than four days, there will be benefit; the average is three to four days, then the rest of the first week's treatment is once a day.

During the second week successful cases come every other day; during the third week twice (there being no treatment between), the fourth

week once, and at the end of the fifth week, if there has been no return of discharge or no gonococci can be found, the patient is given the beer test. He is to drink beer freely—sometimes I make them drink beer every day for a week. Then gonococci are sought for with the microscope, and I have had cases where cultures also were made.

Then—and even this I think important—the patient returns in four to six weeks for a final examination.

I have seen cases in which the gonococcus has disappeared absolutely after the first treatment and not been encountered again; others take a longer time before they disappear from the discharge, and some in which either after disappearing for a time they reappear or do not disappear at all. Still the patient has at no time suffered from the symptoms of the disease; he feels in every way as well as if he did not have the trouble. These cases have some infected follicles within the urethra, usually near the meatus. In other words the impression that I get from this course of treatment is that the disease is throttled at the outset if seen within twenty-four hours; if later, but still before acute symptoms come on, it is checked and kept confined to that portion of the canal already affected, from which it can be only more slowly dislodged.

If the case presents itself later than the third day the disease is practically in full blast, yet even then patients do better with this treatment than any other with which I am acquainted. These patients are frequently made comfortable during the remainder of the attack. Sometimes during treatment certain modifications are necessary. The patient may not be able to come so often, or when the time comes to lengthen the interval of treatment gonococci may return. The patient may then be instructed how to treat himself and be furnished with a ½- to 1-per-cent. solution of protargol to be used once or twice a day at home.

If the disease has made considerable progress before presenting, there is much room for difference of opinion as to whether we shall begin local treatment at once or wait for the decline. Personally I prefer always, if possible, to begin local treatment at no matter what the stage, for the course of the disease can be considerably modified by this treatment and it can be used even when complications are present, though one should know what the limitations are before using it. Of course, we know that the gonococci have penetrated the mucous membrane and only those on the surface are affected, yet all those on the surface of the urethra can be annihilated and those deeper in are removed as they are brought to the surface by the exudation of pus.

The secret of the good to be obtained is due to complete mastery of details and the utmost gentleness and patient deliberateness of technic.

Of course, cases will be found where these remedies seem absolutely impotent and we have to look for assistance from other remedies locally or internally. The diet must be watched carefully and the general health of the patient looked after. For instance, the balsams, if given understandingly, will be of use. I long ago gave up copaiba and cubebs; in selected cases santal oil, obtained from first-class manufacturers, is of assistance. It should be remembered that this is of assistance only and not curative in any sense of the word. As an adjuvant in selected cases it is of great use, and it should never be pushed to the physiological limit. Ten-minim doses of santal oil, three times daily, yield good results, but it should never be used indefinitely. If it does not give prompt action it should be discontinued. When the posterior urethra has become apparently infected a capsule containing one grain of methylene blue and four grains of boric acid has been found of use. The objection to them is the coloring of the urine, which can be kept off the underwear only with the greatest precaution. Salol and oil of gaultheria may also be mentioned. As soon as the posterior urethra has become invaded it is the practice of the writer to treat that locally also. To be of use treatment should be at least once daily, and the time for instituting treatment depends on the condition of the anterior urethra.

Much has been written, however, against irrigation into the bladder from the meatus without the intervention of the catheter. When this can be made without causing discomfort to the patient it is an excellent method, but where the slightest force is used it may be operative of a worse condition than the disease itself. This is due to the utter misconception of the proper manner of performing irrigation of the posterior urethra and bladder without a catheter. Many writers speak of forcing the compressor muscle by hydrostatic pressure. Of course this can be done, but with what an amount of discomfort and injury to the patient. To do this properly we should have the full coöperation of the patient. After the anterior urethra has been thoroughly irrigated the patient is told to urinate just as the fluid is entering the canal. He will thus relax the compressor muscle and while he is doing this the irrigating fluid is allowed to flow along the urethra and will run into the bladder. As soon as the patient has caught the trick the bladder can then be readily flushed from the meatus and urinated out. If the patient does not relax properly this practice should be omitted. The best way to learn this method is to practice upon chronic cases.

Of greater importance is the use of protargol in the posterior urethra. A new soft-rubber catheter, lubricated with glycerin or other soluble lubricant, is very gently passed down to the compressor muscle and filled with protargol to expel the air. No. 12 French is the best size and should have a wide mouth for receiving the point of the syringe. The catheter is then slipped very gently past the compressor muscle into the posterior urethra and from one-half to one ounce of protargol solution (gradually increasing to 2 per

cent.) is slowly instilled into the bladder, being shortly after this urinated out. If the fluid returns about as it was instilled, it shows that the bladder empties itself. Some cases with posterior urethritis, however, do not completely empty the bladder. When this is found to be the case, before instilling the protargol the catheter is to be passed into the bladder with the utmost gentleness and the bladder emptied. The catheter may then be withdrawn from the posterior urethra; the protargol in it will be urinated out as before.

It is especially important that after the necessity for treatment has passed and the patient has gone through the tests that he be instructed to call for examination within six weeks after all treatment has ceased.

CHRONIC GONORRHEA.

BY JOHN VAN DER POEL, M.D.,
OF NEW YORK.

THE field of chronic gonorrhea covers such a vast area that, with the time allotted in a discussion of this nature, it is obviously impossible to consider the subject in all its minute details, or to describe fully the many plans of treatment which have been evolved from time to time. I shall therefore only attempt to study briefly the principles which guide us, and to explain the application of them as far as possible. I must however beg indulgence if, in the following observations, I have not strictly confined myself to that portion of the general subject assigned me; but in order to consider intelligently the treatment, it is essential that we understand the origin, pathology and diagnosis of the disease, at least to a limited extent.

To give a strict definition of chronic gonorrhea would lead us over nearly the entire field of its pathology as well as symptoms; it might perhaps be described as one in which as a consequence of previous gonorrheal infection, there exists a secretion of the urethral mucous membrane and adnexa due to changes in the tissues, which secretion, containing gonococci, is composed of mucus, pus and epithelial cells manifesting itself (1) either by a drop of watery or muco-purulent fluid at the meatus some hours after urination, or upon pressure, the so-called "morning drop," which may be increased in amount and be present at any and all times; (2) by glueing of the lips of the meatus in case there is not sufficient discharge to form a drop; or, (3) simply by the presence of shreds in the urine, the so-called "clap-threads."

Although this is true in the large majority of cases, Hein[1] has shown that the changes in the urethra are present without the evidences just mentioned, but where we find gonococci in the urine, nevertheless.

[1] Read before the New York Academy of Medicine, March 21, 1901.

Not only this, but we know that gonococci may remain dormant in the prostate for months without any outward evidence, and subsequently can, as Frank[2] has shown, cause infection. The etiology must be sought for in the damage caused to the urethral mucous membrane and that of the adnexa by the acute process. The migration of gonococci into the tissues causes but a temporary diffuse inflammation, though as a consequence caused either by the gonococci (or their toxins, according to Friedländer, Christmas, and Wasserman) we subsequently find circumscribed changes in the mucous membrane which give us the picture of chronic gonorrhea. This is especially the case where the powers of resistance have been weakened, even when these cases have been "apparently" healed.

Either through indolence of the patient or on account of a too superfluous examination by the physician, or both, acute gonorrhea is often regarded as cured. If at this period excesses are indulged in, especially alcoholism or coitus, or should the patient suffer from repeated emissions, a return of the trouble is very probable; and the oftener these relapses the less intense but the more persistent they become, with finally a condition of chronic clap.

Frequent fresh infections whose course also becomes modified the oftener they occur, result in the same condition. Finger[3] charges that a chronic condition occurs especially when the acute process covers a large area of surface, *i.e.*, when there is both anterior and posterior infection, on account of the almost universal treatment with injections, without reference to the extent of the process. When the fluid from the ordinary hand injection stopped by the cut-off muscle does not reach the inflammatory process in the posterior urethra, it is thus not treated, and though it becomes less intense does not disappear, but spreads into the prostate by way of the ducts.

In this connection it is important to consider the frequency with which the prostate is involved and thus forms a constant focus for a chronic gonorrhea. That gonorrheal prostatitis is frequent is now admitted by most observers, and doubtless occurs much earlier than is usually thought to be the case. Frank,[4] in a paper read before the Genito-Urinary Section of the last International Medical Congress, stated that it is found involved in many cases as early as eight days after the first symptoms of gonorrhea, in spite of the fact that there may be no subjective symptoms, and in spite of the absolute clearness of the second portion of urine..

The pathological changes which have been demonstrated so well by Kollmann and Finger, consist of an "inflammatory connective tissue formation or hyperplasia," characterized (1) by round small-cell infiltration usually localized about the glands and lacunæ, representing when advanced the granulations seen in the endoscope; and (2) by an atrophy and shrinking of the new connective tissue with the formation of indura-

tions. In other words, the two stages of a cirrhotic formation.

This process can be either superficial, a non-stricture forming scar; or deep, involving the cavernous tissues, a true cirrhotic formation or stricture. This is especially the case anteriorly; while posteriorly the same process extending in the submucous tissue, causes swelling of the caput gallinaginis and chronic prostatitis. Together with these changes we have a proliferation of the epithelium and transformation of the cylindrical into flat, both upon the surface and in the glands, with eventual obliteration and destruction of the latter (Finger).

These conditions can at any time be complicated, either by a relapse into the subacute form, or by a fresh infection.

As for the Diagnosis.—There are several important points to be cleared up before treatment can be commenced, (1) as to the character of the discharge; (2) its origin; and (3) the pathological conditions which cause it.

1. *Is the Discharge "Septic"?*—Do we find upon microscopical examination pus cells and gonococci? *Or* is it in the stage of "secondary infection" with other bacteria coming either from without or from the rectum! *Or* is it so-called "aseptic," of an epithelial nature, with perhaps a few leucocytes and fibrin, for as we have just seen masses of flat epithelium are found as a part of the chronic inflammation, and these together with the mucus from the urethral glands—especially after morning erections, form the "morning drop" or "threads."

2. *The Origin of the Discharge.*—To determine this the so-called Thompson "two glass test" is not sufficient as a rule, as a small amount of secretion may remain in the posterior urethra, and, not flowing into the bladder, does not contaminate the whole amount passed; but thus remaining would be washed out with the first gush of urine, as well as that in the anterior urethra. Hence, it is necessary to resort to the "irrigation test," the washing out of the anterior urethra by catheter before micturition, when if threads are still present, we know that they come from the posterior part. Still further, if the prostatic glands are inflamed, pus and comma-like plugs are often pressed out and appear with, and in, the last few drops of urine, or just after. This can be collected in another glass, the so-called "three glass test" which can be made with or without washing out the anterior urethra.

3. *The Pathological Changes Which Cause the Discharge, Are They Superficial or Deep?*—This can usually be demonstrated by the Otis urethrometer for the anterior urethra; the deeper form very early affecting the dilatability of the urethral walls, while this is not the case if the inflammation is superficial; but the findings of the urethrometer should always be confirmed by the endoscope. Deep chronic posterior disease is often characterized by those symptoms which we call "sexual neurasthenia," *i.e.*, the spermatorrhea of micturition and defecation, prostatorrhea if the prostatic ducts are involved, pain on ejaculation if the ejaculatory ducts are inflamed, precipitate ejaculations, poor erections and frequent emissions, together with a train of nervous phenomena and general depression. Examination of the prostate by rectum will reveal gross changes, and microscopical examination, with cultures of the excretion massaged, will confirm the diagnosis if successful, but will not disprove it if unsuccessful, as in old chronic cases gonococci are often difficult to demonstrate. It should not be overlooked, however, that different portions of the canal may be diseased at the same time, each process in a different stage, and demanding different forms of treatment.

Treatment.

1. *General.*—To lay down a hard and fast rule for the hygienic management of chronic gonorrhea would be impossible. So much depends upon the individual case, and the stage of his disease, that each to a certain extent, must be treated upon its own merits. In general we might say that it is practically that of the acute disease, except that greater freedom may be permitted as regards diet and exercise. Sexual excitement especially should be forbidden, excepting, perhaps, in certain very chronic cases in moderation, in order to allay and avoid congestion which is so detrimental to the furtherance of a cure.

The extremes may be pictured on the one hand in the so-called "sub-acute condition" with a muco-purulent discharge containing gonococci, where it is obvious that a relaxation of the rules necessary in the acute trouble—excepting in the most inflammatory stage—would be contra-indicated; and on the other hand in anemic, poorly-nourished and debilitated individuals, either originally so or as a result of a long course of local and internal treatment, with mental worry and consequent malnutrition, with a flabby or so-called "leaky condition" of the mucous membrane, where tonics, alcohol in moderation, exercise—excepting the horse and bicycle—and general constitutional stimulants will, in some cases be more effectual than any amount of local treatment. Between these two, each case must be judged upon its individual merits; the personal equation and the patient's experience often being of considerable assistance.

2. *Internal Treatment.*—The rules which guide us here are also very similar in principle to those of the acute stage: alkalies and diluents in case of scalding, if re-infection is present; oleoresins when this has subsided; and later, antiseptics, as salol and urotropin.

3. *Local Treatment.*—General rules to be observed in all cases are: (1) Care and conservatism in all procedures; (2) avoidance of over-instrumentation and injuries to the mucous membrane; (3) sufficient rest after passing through one system of treatment before beginning another in case the other is necessary; (4) regular and systematic use of the microscope in the con-

trol of the treatment—this is most essential; (5) surgical cleanliness, and sterilization of all instruments.

Local Procedures.—These should be directed against (1) the *gonococci;* (2) *other bacteria* in case secondary infection is present; and, (3) *the anatomical lesions,* the results of the gonococci and their toxins with the restoration of the tissues to their normal condition as far as possible.

Before considering the purely chronic disease with localized lesions in contradistinction to the acute, where they are diffuse, it is first necessary to study that condition known as "subacute" directly from which the chronic is developed, and by which it can at any time be complicated. "This, a still more or less diffuse process, but with the localities which are to be the seat of chronic trouble in the first stage of inflammatory hyperplasia, is characterized by a still considerable number of pus cells, or many and heavy shreds in a cloudy urine" (Finger).

The points in particular where the tendency to localize is most marked are the "fossa navicularis" and the "bulb," especially the latter where pus is more prone to collect. Should there be any doubt as to the significance or morphology of any diplococci which may be found, the "Gram test" or method of staining is our best means of a differential diagnosis.

The best remedy at our disposal at the present day for destruction of the gonococci is protargol. The ordinary urethral syringe, of good service in some conditions, is not sufficient for a thorough washing, as with it a complete unfolding of the mucous membrane is scarcely possible, and much to be preferred is the system of irrigation with the fountain syringe, one point in the technic of which should be mentioned, *i.e.,* where the anterior urethra alone is being washed out in order that the folds may be obliterated, it is necessary not only to draw out the glans from the body, but the urethra should be thoroughly filled by alternately relaxing and pressing the beak of the instrument against the meatus.

If, however, the posterior urethra is also involved, the irrigation must reach the bladder, when it is better to avoid spasm of the cut-off muscle by the use of cocaine, 10 to 15 grams of a 1-150 solution held in the anterior urethra for four or five minutes, generally being sufficient to accomplish this purpose, when the irrigation can be made either with a fountain syringe, or with what I usually prefer, the large urethral syringe holding 150 grams, known as the "Ultzmann syringe," but now modified (by Janet, Frank and others) so that it is sterilizable, and to which blunt porcelain tips are fitted in order not to injure the mucous membrane.

The discharge of pus in the urine in considerable quantity, together with scalding, indicates that a considerable area of mucous membrane may be inflamed or irritable, and that urethral instrumentation should be avoided if possible—a rule in all stages of gonorrhea.

The strength of protargol employed is from ½ to 1½ per cent, for the anterior urethra, and from ½ to 1 per cent. for the posterior; the amount for the anterior, 500 to 1,000 grams; for the posterior, 200 to 500 grams. The injections are made daily, but I have found that they are most effectual when combined with hand injections of weak bichloride of mercury, from 1-30,000 to 1-15,000 made by the patient himself.

It is most important, however, that the capacity of a hand syringe be sufficient to thoroughly fill the anterior urethra; the small variety ordinarily employed being frequently useless, holding usually but 4 to 8 grams (1-2 drams), whereas they should hold 10 to 15 grams (3-4 drams). In prolonged cases with the lessening of the pus in the discharge, diminish the strength of the protargol, it previously perhaps having been carried to 1½ per cent. depending greatly upon the sensitiveness of the patient. Likewise with the frequency, with the lessening of the pus, they are given less frequently, every second, third or fourth day, and, finally, once a week; in this manner in a large number of cases, not only the discharge but the filaments in the urine disappear. The diminishing of the strength of the solutions and the lessening of the frequency of administration, are most important, as it must be remembered that a so-called "chemical catarrh," the result of injections, may be kept up where no gonococci or other bacteria are to be found.

Should the discharge or shreds which remain have been freed of gonococci after repeated examination, we are in what Janet[5] terms the "aseptic stage"; but should as is so frequently the case, other bacteria—staphylococci usually—be present, then we have the so-called "secondary infection."

When secondary infection is present I have found the best results attained from bichloride of mercury in the strengths just mentioned, or even slightly stronger, used as an irrigation by either of the two methods; but as with the protargol in the previous stage, after increasing the strength it should again be diminished as should also the frequency of the washings or irrigations. When other bacteria are no longer to be found, or have not been present, weak solutions of astringents, such as nitrate of silver, sulphate of zinc, or acetate of lead, may be used with the hand syringe; or weak bichloride as a douche. At this stage, a very excellent method is the washing out with the so-called "Ultzmann solution" either by the methods just mentioned; or, by injecting it into the bladder with a soft rubber catheter, allowing the patient to void the fluid afterward. This solution consists of one part each of zinc sulphate, alum, and carbolic acid, to 1,000 parts of water.

Should discharge or shreds still persist after a fair trial of the treatment thus outlined, a period of rest is indicated before instituting more localized procedures for the reason just mentioned.

As to truly *chronic cases,* where the disease is distinctly localized, the plan of treatment to be developed should be guided by (1) the anatomical character—whether we have a superficial inflammation, or an infiltration of the deeper tissues—and (2) the localization of the process—whether in the anterior, or posterior urethra, or both.

The superficial circumscribed and succulent patches of mucous membrane can be treated by the application of concentrated astringents or caustics, localized as much as possible in order to bring about re-absorption. These can be carried to the diseased portions either (1) by the various so-called "capillary syringes," or by means of brushes with especially adapted instruments; (2) in the form of ointments and less solid fats by the instruments of Lallemand and Tomassoli; (3) with the aid of the endoscope by applicators with cotton.

The solutions employed in the various capillary syringes (either that of Guion,[6] the original Ultzmann instrument, Friedländer's combination of the two,[7] Oberländer's removable silver tipped instrument,[8] Bang's[9] syringe, which I prefer, with that of Guion; or the soft catheter employed by Taylor[10]) are usually nitrate of silver from ½ to 5 per cent., or sulphate of copper of about the same strength; the amount, from 2 to 10 minims; the frequency not oftener than three times a week, usually twice and sometimes but once, or less frequent, beginning with the weaker solutions, being guided by the sensations of the patient and the results of treatment; and never giving a second injection until the symptoms of irritation from the preceding have subsided. After a few weeks allow the patient to rest.

The employment of ointments or fats as vehicles for medication, although by some considered less sure and more uncertain as to results, is recommended by its advocates most hightly. For this purpose nitrate of silver can be used in the same strength as in the watery solutions made up with lanoline and sufficient olive oil to render it fluid at ordinary temperatures.

The use of the endoscope has occupied a very prominent position in modern therapeutics of the urethra; but it has its limitations and should not be used indiscriminately.

As a general rule we might say that being a procedure the action of which is local, its application should be limited to localized lesions—those macroscopically visible. I shall not enter into advantages and disadvantages of the various instruments, as with the most of the modern ones—especially those devised by our American colleagues—when in the hands of competent men, good work can be done, as also with the speculum of Tilden Brown which has proved itself most useful. As said, the field of usefulness of the endoscope is a limited one, but not so limited as some of its opponents would have us believe, though considerable experience and practice are necessary to be able to recognize the pathological from normal tissues. I can do no better than quote Klotz[11] as to its use when he says: "It is principally indicated in those superficial inflammations in which circumscribed patches of the mucous membrane, wherever located, have undergone certain changes which cannot be effected any more by the usual injection of astringents or parasiticides, because those remedies are powerless in the solutions which may be syringed into the urethra without injury to the healthy portions. By using the brush or applicator and cotton we may apply much stronger solutions or powder or even caustics to the diseased spots and to them alone."

The remedies which may be used are limited only by the Pharmacopœia, and it is difficult to explain why one will act well in one case and not in the other. With involvement of Morgagni's lacunæ and the glands of Littré, when the pits are depressed below the surface, the endoscope or speculum is invaluable, as lavage and injections will not reach them, and they may form foci of repeated infections. These may be treated with solutions with Kollmann's urethral syringe, with the knife, cautery or electrolysis.

Later on polypi and condylomatous growths—which are rather rare but sometimes the cause of a chronic discharge, or perhaps hemorrhage, are removed with the cautery or instruments especially devised, as that of Denos.[12]

The endoscope, however, as with other methods is not infallible. Generally speaking it should not be used until other means have failed us, unless required by special indication.

When the pathological changes have gone deeper than the surface, when examination shows the presence of an infiltration or perhaps already the formation of a cicatricial tissue, it is very evident that it is a thankless task to reach it by means of astringents applied superficially; for although we may get temporary results we do not get "at the bottom," so to speak, and slight causes may bring on a recurrence of the symptoms.

The principle to be employed in these conditions is "dilatation combined with irrigation with astringents or parasiticides." In its simplest form this can be carried out with a steel sound followed by injections or the use of the fountain syringe, remembering that when treating the anterior urethra alone, it is unnecessary to go into the prostatic urethra. In recent years this dilation with more complicated apparatus has been done, first by Oberländer[13] with his two-bladed instrument, and more recently with the Kollmann[14] four-bladed dilator, or Valentine's[15] recent modification of the latter. These are to be preferred to the sound in many cases, because the meatus is too small to pass a sufficiently large sound to exert the amount of dilation necessary; and because when dilating a special region, as the bulb, to some considerable extent, it would be needless and harmful to exert the same pressure over a too large area. Kollmann's irrigating dilator, where both steps can be done at once, will be found useful in many cases. The dilators are made in different shapes according to the anterior or posterior urethra, or both; and when in

use are provided with a rubber covering (excepting the irrigating instrument) to prevent catching the mucous membrane while being closed. The first stages, however, can be accomplished more easily and with less danger with sounds, these being increased in size very gradually up to No. 30 or thereabouts, cutting the meatus if necessary beforehand, and after each sitting washing out the urethra with astringents as just mentioned. Dilatation with the dilator proper, must be done *gently, gradually* and *without force,* to avoid injuries and tears in the mucous membrane. It should not be applied oftener than once a week. Frank's rule where both anterior and posterior urethræ are at fault, to dilate them alternately every three days, being a good one. Contra-indicating symptoms are pain, hemorrhage and increased discharge. The length of the sittings is from five to twenty minutes *increasing but one number of the scale each time.*

As with the sounds, astringents are again used immediately following (excepting with the irrigating instrument) either weak, by irrigation, or concentrated, with the assistance of the endoscope, as recommended by Klotz; or, if posteriorly, with a capillary syringe. Pain can be greatly controlled with cocaine before operation. The astringents best employed are bichloride of mercury, silver, or the Ultzmann solution, preferably the former, to prevent secondary infection; and this should also be given the patient for use as hand injections between the sittings. A sudden increase of discharge containing gonococci indicates that we have probably ruptured an encapsulated gland containing gonorrheal pus, or perhaps a re-growth even from a single coccus causing a re-infection, the first, practically an advantage to have gotten rid of another focus.

Never use the dilator as long as gonococci are present, excepting, as Bierhoff[16] says, "in those cases in which endoscopy has shown that the glands and crypts and tissues immediately surrounding them are the seat of the trouble, and then only with the irrigating dilator."

Nor should it be used when other bacilli are present. In superficial chronic posterior urethritis, after the gonococci have been gotten rid of, it is useful in removing the infiltrate; but, as Bierhoff again states, "as in over 90 per cent. of chronic disease of this region the focus of disease is in the prostate, dilation is not only useless but positively harmful." Valentine's[23] statement "that all cases of chronic gonorrhea are not cured by it, but that a large number being due to infiltration of the crypts, glands and surrounding tissues, either yield or are greatly benefited by it" I believe true.

Chronic inflammation of the posterior urethra on account of the anatomical character of that region, unfortunately does not, as a rule, remain superficial; the mucous membrane instead of being richly supplied with glands and lacunæ, is in close anatomical connection with the prostate, and it is but a short distance by way of the ducts to the glandular structure itself. Frank[17] states, that in 631 cases of gonorrheal urethritis, the posterior urethra was involved 210 times, or 32¼ per cent.—nearly one-third—though a number of these had previously suffered from posterior disease. In all the 210 cases the prostate was diseased, *i.e.,* 100 per cent.; and in the 210 gonococci were found 179 times, other bacteria 20 times, and aseptic secretion with leucocytes 11 times.

Personally, I am not prepared to offer any statistics that would tend either to confirm or deny these figures, but am convinced by recent observation that involvement of the prostate is of very frequent occurrence, and in the majority of which cases gonococci were demonstrated in the expressed fluid.

As irrigations and instillations will not reach the gonococci when in the prostate, it is evident that we must resort to other means, and this is primarily accomplished by prostatic massage followed by washing out of the bladder and posterior urethra. More recently faradism has been added to the massage, instruments for which have been devised by Hogge,[18] Janet,[19] Frank,[20], Guiteras,[21] and Freudenberg,[22] the latter being an arrangement by which the electricity is passed through the finger of the operator as one pole, which at the same time accomplishes the massage. If the mouths of the glands and ducts have become constricted by surrounding inflammation, and plugged with inflammatory products causing a cystic condition of the glands themselves, the results of treatment will be less rapid. Until we have, however, after repeated trials been unable to demonstrate the presence of gonococci in the expressed secretion, we are not justified in concluding that this part of the genito-urinary apparatus can be eliminated. Care and conservatism in performing the massage, with sufficient intervals between the sittings, are to be borne in mind. Acute inflammations and abscess are naturally contra-indications to this form of treatment.

That a large number of chronic gonorrheas, speaking generally, remain uncured, is undoubted; some of these may be explained by the indolence or the discouragement of the patient, others by want of care or understanding on the part of the physician, others by reason of constant re-infection, either from the wife or mistress, and still others from no tangible cause, all gonococci having "apparently" been eliminated.

I have not been able to consider every hypothetical case of this extremely important disease, the principles govering the treatment of which, if more generally comprehended by the profession, would, I believe, do much toward the limitation of infection in the opposite sex, and the consequent long train of gynecological disturbances and oftentimes sterility.

ON GONORRHEAL CONJUNCTIVITIS.[1]

BY WARD A. HOLDEN, A.M., M.D.,
OF NEW YORK.

The treatment of gonorrhea of the conjunctiva has followed the swing of the pendulum like the treatment of gonorrhea of the urethra. A generation ago strong solutions of nitrate of silver were applied to the conjunctiva from the very incipiency of the disease. Then a reaction took place in many quarters and the disease in the acute stage was treated exclusively with cold applications and irrigation with mild antiseptic solutions. Recently there has been a general return to the use of the astringent and coccus-destroying silver preparations, but in the place of the caustic and irritating nitrate, which is so painful when applied to the conjunctiva, blander preparations, such as protargol and argentamin, are now very generally used.

The course of untreated gonorrheal conjunctivitis and the complications to which it often leads may be described in a few words. From one to four days after infection the first signs manifest themselves in a swelling of the lids and, in adults, a thin, watery discharge. The lids then continue to swell until they may become brawny, when eversion is impossible. The conjunctiva of the eyeball, too, becomes edematous, flakes of mucus appear in the discharge, and the patient experiences considerable discomfort. A day or two later, whether in the new-born or the adult, a thick creamy purulent discharge fills the conjunctival sac, floods the cornea, and pours out through the aperture of the lids. At this early stage the nutrition of the cornea is interfered with and it sometimes sloughs, breaking down, it may be, in the course of a few hours, as it does sometimes in the keratomalacia of poorly-nourished infants suffering from fatal diarrhea. After the purulent discharge is established the swelling and tension of the lids diminish, but the conjunctiva remains swollen, and velvety from a hypertrophy of its papillæ. The parenchyma of the cornea may now become diffusely hazy or superficial ulcers may appear which rapidly extend deep and often lead to perforation of the cornea with all its disastrous consequences. The purulent discharge gradually decreases and in the course of several weeks may cease, but a chronic papillary hypertrophy of the conjunctiva still persists.

The purposes of treatment are threefold, the checking of a contagious discharge, the prevention of complications on the part of the cornea, and the avoidance of infection of the second eye if this is still healthy. The ideal treatment, if it can be carried out, is as follows: When a patient with suspected gonorrheal conjunctivitis is first seen, the discharge should be examined microscopically. Frequently a man with a urethral discharge acquires an innocent conjunctivitis caused by the Weeks bacillus or the pneumococcus, and if the benign nature of such an inflammation is not determined at the outset much needless anxiety may be suffered. At the very beginning of the disease a single application of nitrate of silver, two per cent., or of protargol, forty per cent., may modify favorably its subsequent course. The chief indication, however, in the early stages is cold. The patient is kept in bed, and patches of lint, absorbent cotton, or folded linen that have lain on a lump of ice are applied to the closed lids, and changed every niinute or two, day and night continuously. This is most essential during the stage of extreme swelling of the lids. Besides this, the conjunctival sac is irrigated every few minutes, or as often as is necessary to keep the eye free from secretion, with a warm saturated solution of boric acid or a 1-2000 solution of permanganate of potassium. These solutions are dripped into the eye from a pledget of cotton without the use of any instruments that might abrade the cornea. In infants, too much cold may injure the cornea and hence the iced applications are changed less frequently or used less continuously. The cornea is inspected at least once a day and at the first sign of haziness the cold applications are decreased or even warm ones may be substituted and atropine is instilled.

When one eye only is affected the other is protected from infection by a transparent shield attached with adhesive plaster or by an ordinary dressing which is rendered impenetrable to pus by gumming down its edges with collodion.

If the attending physician elects to use nitrate of silver this is brushed over the conjunctiva of the everted lids, in a one- or two-per-cent. solution, once or at the most twice daily as soon as the swelling has diminished sufficiently to allow the lids to be everted. This is continued until the discharge is checked, when a weaker solution may be used for the persisting papillary hypertrophy.

The manner of using protargol is not yet conventional and uniform. It may be employed,

[1] Read before the New York Academy of Medicine, March 21, 1901.

however, from the beginning of the disease without causing the irritation and pain that follow the use of silver. Some ophthalmologists apply a twenty- to forty-per-cent. solution to the everted lids once or twice in the twenty-four hours. Others apply a five-per-cent. solution once daily and have a three-per-cent. solution dropped into the eye every four hours, and still others have a five-per-cent. solution dropped into the eye three times daily. Some who have used weak solutions only are so skeptical as to declare that, while protargol is unirritating, it is also inefficacious, but recent comparative statistics seem to show that if used in sufficient strength protargol cures the disease in a shorter time than silver and with less discomfort.

When ulcers of the cornea develop and appear to be infected they are touched with tincture of iodine, carbolic acid, or the actual cautery; and perforation of the cornea with prolapse of the iris is treated as are cases of perforating ulcer from other causes.

Obstetricians and midwives, unfortunately, do not always take ophthalmia neonatorum seriously. Furthermore, the Credé method of dropping a two-per-cent. solution of nitrate of silver into the eyes of the new-born is not always a preventive. Many of these little patients are brought to us with the cornea already affected, and such eyes frequently are lost. Only a few days ago, for example, a mother who had not been warned of the gravity of the disease brought her neglected infant two weeks old to the Vanderbilt Clinic with the cornea of each eye wholly sloughed away, which, of course, means permanent blindness that might have been prevented. And such cases are not uncommon.

Unfortunately, too, many patients with gonorrheal conjunctivitis cannot be treated properly because of the lack, long deprecated, of a special public hospital in New York for contagious diseases of the eye. A patient with gonorrheal conjunctivitis requires nursing night and day; he should not be kept in a ward with ordinary patients, and his nurse should not be allowed to attend other patients. Therefore, most hospitals admit these patients under protest and with restrictions, if at all, and thus many of the patients who apply at the dispensary must be treated unsatisfactorily as out-patients. Patients may be sent, it is true, to the City Hospital on Blackwell's Island if they are willing to go there, and a special ward for contagious diseases is in operation at the Manhattan Eye and Ear Hospital, while a new detached pavilion for contagious diseases of the eye, which is a model of its kind, has just been opened at the New York Eye and Ear Infirmary. Still, at present, it is clear that conditions are not as we would wish them, and we feel sure that if patients with gonorrheal conjunctivitis were always sent to us before corneal complications had arisen, and if there were always convenient hospital facilities for the care of serious cases and such as cannot be treated properly at home, the number of the dependent blind would be greatly reduced, and the enormous expense of suporting them throughout their lives in an asylum would be in no small degree curtailed.

The establishment of a public hospital in New York for the treatment of contagious diseases of the eye is most desirable as a purely economic measure, to say nothing of its humanitarian features. But, economically, it is even more desirable that all who attend women in labor should realize the importance of preventing gonorrheal conjunctivitis by disinfecting the eyes of the new-born, and when, nothwithstanding, exceptional cases do develop, of having them treated with intelligence and without delay.

TREATMENT OF GONORRHEAL STRICTURE OF THE URETHRA.[1]

BY JAMES R. HAYDEN, M.D.,
OF NEW YORK.

The treatment of gonorrheal stricture varies greatly in different cases, depending both upon its situation in the canal, and whether it be soft and yielding, or dense and fibrous in character; therefore, before adopting any plan of treatment, the surgeon must first ascertain by careful urethral exploration, the location, consistence, extent and caliber of the contraction and also, from a urinary examination, the condition of the kidneys, and at the same time the extent and severity of the urethral and bladder inflammation, which latter points are of paramount importance in regard to the patient's ultimate cure, and which, strange to say, are frequently ignored or overlooked by the operator, who apparently considers that dilatation or cutting is all that is really essential, and that a chronic urethritis or urethrocystitis is of little or no importance. The condition of the prostate gland, the seminal vesicles, and in fact all of the structures opening into the urethra must be ascertained, and appropriate treatment instituted if diseased conditions are found.

As a broad general rule, it may be safely stated that the best routine treatment for recent and even fairly-recent cases of gonorrheal stricture, is careful and gradual dilatation, combined with instillations or irrigations, and appropriate diet and internal medication to render the urine bland and non-irritating; if gradual dilatation fails, or for any reason cannot be employed, we then resort to one of the cutting operations about to be described, being guided in our choice of procedure by the location and extent of the contraction, which is readily ascertained by the *bougie à boule*.

For clearness and conciseness of description we will first consider stricture of the meatus; second, stricture of the pendulous urethra, and, third, stricture of the bulbous portion and at the bulbo-membranous junction.

Stricture of the Meatus.—As a general rule

[1] Read before the New York Academy of Medicine, March 21, 1901.

stricture of or just within the meatus does not yield to dilatation and must therefore be incised by meatotomy in the following manner: The patient having urinated, the external genitals are thoroughly cleansed, as is also the anterior portion of the urethra by irrigations of boric-acid or salt solution and the parts surrounded with sterile towels. Local anesthesia is produced by injecting a little cocaine solution into the fossa navicularis; the contracted meatus is then slowly incised with a straight, blunt bistoury downward on its floor and directly in the median line up to about No. 28 or No. 32 of the French scale; according to the requirements of each individual case; contractions in the fossa navicularis are dealt with in the same manner, except that an incision may have to be made in the median line of the roof, as well as in the floor of the canal. The urethra is then irrigated, and a full-size sound passed beyond the wound. A snug dressing of sterile gauze prevents subsequent bleeding from the little incision, which should be kept open and made to heal from the bottom, by the daily passage of full-sized sounds.

Stricture of the Pendulous Urethra.—If the contraction is soft and yielding it should always be treated by gradual dilatation with soft bougies until we have reached about No. 18 of the French scale, when steel sounds are to be substituted. As a general rule it is best to practise dilatation every fifth or seventh day, leaving the instrument in place for several minutes in order to exert pressure and dilatation on the stenosed and thickened urethral walls; these patients should also have instillations or irrigations of silver nitrate which are of the greatest value in bringing about a healthy condition of the infiltrated urethral and peri-urethral tissues.

If, after a careful trial, gradual dilatation fails, the stricture must then be cut by internal urethrotomy in the following manner: The patient, having urinated, is anesthetized and the external genitals and urethra prepared for operation in the usual manner. If the stricture is fairly near the meatus it can be cut with a straight, blunt bistoury, but, if further down the canal, with any good urethrotome, according to the size or caliber of the constriction and also the surgeon's personal preference for any special instrument; the important point to remember in this operation is that the cutting instrument should always be held firmly in the median line, and the penis pulled out over it, and well on the stretch, so that the incision will be as nearly as possible in the middle line of the roof of the canal, which should be cut up to about No. 25 or 30 of the French scale, rarely higher. A full-sized sound or *bougie à boule* is now passed to see that all is clear and the urethra thoroughly irrigated with warm boric-acid solution, several ounces of which are thrown into the bladder and left there, so that the first urine passed will be fairly well diluted. The subsequent treatment consists in the frequent passage of full-sized sounds and the employment of irrigations or instillations, according to the requirements of the case, until the urine is clear and the urethra taking reasonably large instruments with ease, when the intervals are made much longer.

If after the operation the patient shows any signs of urethral fever, all of the urine must be carefully drawn with sterile catheters, and the bladder and urethra irrigated with warm sterile and non-irritating solutions, and urotropin, or boric acid, administered by the mouth in full dose.

Strictures in the Bulbous Urethra, and at the Bulbo-membranous Junction.—Strictures in these regions, as in the penile urethra, should if possible be treated by gradual dilation and local medication; if, however, they are fibrous, dense and unyielding, then external urethrotomy or perineal section is the operation of choice, as by it the contraction is thoroughly incised and the bladder and bulbous urethra are freely drained, thus obviating the danger of urinary infection; the same end can also be accomplished by first cutting the stricture from within (internal urethrotomy) and then doing a small external urethrotomy for drainage; personally, however, I see no advantage in this double procedure over an ordinary external urethrotomy in which the stricture is cut and the bulb and bladder drained at the same time.

External urethrotomy having been decided on, the patient is kept quiet for a day or so before the operation, and put on a light nourishing diet with perhaps strychnine and quinine in full doses. Alcohol must be stopped or taken in great moderation, and the urine rendered bland and sweet by plenty of water and proper internal medication. The urethra and, if possible, the bladder should be irrigated daily with boric-acid or mild silver solutions. The bowels must be kept open and, on the morning of the operation, the rectum emptied by means of an enema.

Operation.—The external genitals and perineum having been properly prepared, the patient is etherized and placed in the lithotomy position. The urethra and, if possible, the bladder are irrigated with boric-acid or salt solution, and the surrounding parts covered with sterile towels. If possible a tunneled sound, or, that failing, a filiform bougie is passed through the stricture into the bladder and held there by an assistant who at the same time retracts the scrotum. An incision is then made in the median line of the perineum down to the urethra, which is opened on the guide by a single clean cut, and all of the stricture tissue carefully incised not only on the floor but also on the roof of the canal. The index finger is now passed into the perineal wound and backward on the roof of the canal into the bladder, as on its way it readily detects any bands or

masses that have not been thoroughly divided. The dilatation of the posterior urethra by the index finger prevents in a great measure post-operative tenesmus with painful efforts to expel the tube. The perineal operation being completed and bleeding controlled, a full-sized sound should be passed from the meatus into the bladder in order to ascertain that the whole length of the urethra is clear; if obstructions exist, they may be removed by meatotomy, internal urethrotomy, or post-operative dilatation.

A large soft-rubber perineal tube is introduced into the bladder just far enough to allow the urine to drain freely, and secured in place by a heavy silk suture passed directly through it and both edges of the wound, which is then lightly packed with gauze, and the suture tied. The bladder is then irrigated and partially filled with boric-acid solution and the tube clamped until the patient is put to bed, when it is attached to the usual siphon apparatus, and an opium suppository administered.

On the second day after the operation the tube is taken out, washed and replaced; it is removed permanently on the fourth or fifth day and the patient allowed to be up and about and passing his urine both by the urethra and the perineal incision. In the majority of cases all of the urine is passed by the urethra in about one week after the removal of the tube, although in some the urethral wound remains patulous for a longer period.

When the tube is first taken out for cleaning, a medium-sized sound is passed to the bladder; this is repeated regularly every second or third day, until the perineal wound is cicatrized, and the urethra taking a No. 28 to 31 French with ease, according to the case, when the intervals are made longer. After the sound is removed the tube is replaced and the bladder and urethra irrigated with boric-acid solution, and on the alternate days, if indicated, with a mild solution of nitrate of silver. The perineal wound should be inspected every day to see that it is healing solidly from the bottom by firm, healthy granulations. When the perineal wound is cicatrized, the urethra taking a full-sized sound with ease and the urethrocystitis improving, the patient must be made to understand clearly that the operation has not cured his stricture, but merely divided it, and that he must continue to have sounds passed at long intervals (once or twice a year) for the remainder of his life; also that he must not stop bladder or urethral medication until urination is normal and the urine practically free from tissue elements.

If at the time of the operation it is found impossible to pass any instrument through the stricture, a grooved staff or tunneled sound may be passed down to the anterior face of the contraction and the urethra opened on the groove of the instrument just in front of the stricture; the cut edges of the urethral wound being separated by long silk ligatures passed through them. The staff is now withdrawn and the ligatures retracted, which gives the operator a clear view of the anterior face of the stricture, which is carefully examined for its opening by means of a fine grooved director, or filiform which is passed through it into the bladder. The stricture is then divided with a small bistoury, and a full-sized sound passed from the meatus.

If, however, the opening in the stricture cannot be found the surgeon will have to complete the operation without a guide, cutting through the stricture slowly and carefully in the median line with perhaps the left index finger in the rectum, which keeps the operator informed as to the proximity of the gut and also the position of the apex of the prostate gland. The mucous membrane of the roof of the urethra is also a serviceable guide, as it can be plainly seen and felt.

In those rare and exceptional cases which will not admit of the passage of any instrument through the anterior urethra, we are compelled to do an external urethrotomy without a guide, or, more correctly speaking, a true perineal section. The patient being in the lithotomy position, the left index finger is introduced into the rectum and its tip kept in contact with the apex of the prostate, the operator cutting down to the urethra by careful dissection, as in an external urethrotomy. The canal having been found and opened, the index finger is passed through the perineal wound into the bladder, and all of the stricture tissue thoroughly divided. In those old and neglected cases of gonorrheal stricture, in which the perineum is riddled with urinary fistulæ and sinuses, and in which the urethra is converted into a fibrous cord, and cannot be entered by the perineal route, the surgeon may resort to retrograde catheterization, through a small suprapubic incision. These advanced cases, however, are seldom met with at the present time, except in hospital practice, and then but rarely. The drainage and the subsequent treatment in these latter cases are precisely the same as described for simple external urethrotomy with a guide.

Miscellaneous Methods of Treatment.—Under miscellaneous methods of treatment may be mentioned rapid dilatation, continuous dilatation, divulsion, electrolysis, and urethrectomy.

If the stricture will admit of the passage of a filiform, it may be left in place as a guide, and tunneled sounds of increasing sizes passed over it through the stricture, which can in this manner be *rapidly dilated* at one sitting provided it is not too fibrous. This method of treatment is attended with risk, and should therefore never be employed except in an emergency, and unless the patient can remain in bed and be under the surgeon's personal observation.

Any instrument, no matter how small, that has been passed through a tight stricture, may be retained for a few hours, or even a day or so, as by its *continuous dilation* it frequently acts most satisfactorily on the thickened area and is therefore of service in certain selected cases.

The treatment of stricture by *divulsion* or *rupture* with especially constructed instruments is, to say the least, bad surgery, and is too rough, dangerous and inexact ever to be advised or employed.

As *electrolysis* is only of questionable service in strictures of the soft variety, it is merely mentioned to be condemned, as in this variety of cases most satisfactory results are obtained by gradual dilatation and urethral medication. It has practically no effect whatever upon dense fibrous strictures which always demand free incision either from within or without.

By *urethrectomy*, the stricture tissue is excised or resected at the time of the external urethrotomy or perineal section, and a new urethra built up and around a retained soft rubber catheter or tube. This method, if employed at all, should be reserved for those cases in which there is a great deal of localized and dense fibrous tissue about the canal.

THE TREATMENT OF THE COMPLICATIONS OF ACUTE GONORRHEAL POSTERIOR URETHRITIS.[1]

BY JAMES PEDERSEN, M.D.,
OF NEW YORK;
ASSISTANT ATTENDING SURGEON (G. U.) BELLEVUE HOSPITAL; ADJUNCT PROFESSOR OF VENEREAL AND GENITO-URINARY SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, ETC.

Of the topic for the evening the division that has been assigned to me by the courtesy of our President will admit of subdivision into local complications and remote or general complications. The local complications are: Urethrocystitis, cystitis, ureteritis, pyelitis, pyonephrosis, funiculitis, epididymitis, prostatitis and seminal vesiculitis. The general complications include: Arthritis, endocarditis, pericarditis, pleuritis, meningitis, iritis and certain rarer inflammatory affections of the eye; but the limitations prescribed for this paper require that of these only arthritis, otherwise gonorrheal rheumatism, be considered, it being the most common manifestation of the systemic infection.

The local complications, through continuity of tissue, are peculiarly interdependent. Certain ones are intimately so and, in consequence, scarcely admit of distinction as entities. Hence it is convenient to take them up in the order of anatomical sequence, though thereby the most frequent be brought into apposition with the most infrequent.

Before considering the treatment of each in turn it will be well to enumerate certain essentials common to the treatment of all. The underlying physiological principle is: The avoidance of whatever directly or indirectly, by irritation or stimulation, excites in the genito-urinary system hyperemia or congestion. Therefore abstinence from sexual excitement, passive as well as active, recumbency, bland and antiseptic urine, regular, easy stools, an exclusive milk diet, abstinence from alcohol, tobacco and coffee, and no instrumentation nor irrigations, are the ideal fulfilments of the primary indication. So far as possible they should be realized, but the law of compromise cannot be set aside. Antiseptic urine can be approximated only; the exclusive milk diet may have to give way to a mixed fluid diet; alcohol, tobacco and coffee—any one or all three—may have to be reduced before they can be removed, depending upon the patient's dependence upon them.

As to instrumentation and irrigation, whether or not the gonococcus, unaided by some other form of infection, is capable of invading the genito-urinary organs beyond the confines of the urethra, authorities are not agreed; but they are agreed that the traumatism of instrumentation favors each and every infection, causing as it does abrasions and congestion if no higher grade of inflammation. Therefore instrumentation is deprecated, and when, for the relief of the patient's sufferings, surgical intervention by instrumentation or otherwise becomes imperative, any crude or coarse manipulation is a perversion of the last resource. Reduced to rule, the more skilful and the more conservative the local treatment of any infected region of the genito-urinary tract, the greater the prophylaxis for the endangered contiguous region. Finally, throughout the course of any complication, the patient's general health and vital resistance should be maintained as high as possible.

Urethrocystitis implies that the trigonum has become involved by extension of the inflammatory process from the posterior urethra. The term is not in common use, the symptoms and treatment of posterior urethritis and this complication in their acute stage being so nearly identical that they rarely are differentiated in the average clinical history.

In the treatment the chief indication is bland and antiseptic urine. This is met by a milk diet, water between meals, and the so-called urinary antiseptics. If the patient cannot tolerate an exclusive milk diet a demulcent drink offers a compromise. The quantity of this and of water to be taken as a diluent depends upon the quality and reaction of the urine, and the severity of the tenesmus in the given case. The object is to render the urine bland without unnecessarily augmenting the quantity, whereby the patient's urinations would be multiplied and his sufferings increased. The question of giving alkaline

[1] Read before the New York Academy of Medicine, March 21, 1901.

diuretics will arise. As a rule they are not necessary. A strongly alkaline urine is not demanded by the indications. On the contrary, it is distinctly contra-indicated, because it invites infection of the bladder, especially if there is any retention, and, secondly, because it antagonizes those most valuable urinary antiseptics—urotropin and cystogen. The best substitute for either is salol in full dose.

In spite of the bland urine the tenesmus may be so severe as to require anodynes. Hyoscyamus, belladonna or atropine, and morphine, by rectum, by mouth or hypodermatically, are the only positive ones. Upon the too-ready use of the last-named should attach the restriction that with a *neglected* urethrocystitis complicated by a stricture not infrequently begins the habitual use of the drug.

As to local treatment, a moderate number of cases do well without any during the acute stage, aside from hot sitz-baths and fomentations, the general treatment sufficing to carry them through comfortably. In a second class of cases the severity of the symptoms will suggest the use of rectal irrigations of normal salt solution in temperature from 105° to 120° F., by means of the Kemp, the Guiteras, or Chetwood tube, once, twice or three times a day. The teasing desire to urinate and the tenesmus often are lessened by this means. A third class, that in which there are extreme frequency, urgency and tenesmus with bloody urine—a few drops of which are squeezed out every ten or fifteen minutes—demands in addition something more radical. The patient's suffering makes instrumentation imperative, there being no alternative. After washing the glans penis and anesthetizing the penile urethra, a smooth, blunt, sterile soft-rubber catheter, lubricated with lubrichondrin (glycerin irritates some urethræ), is passed into the bladder slowly and with the utmost gentleness. The obstructing spasm that usually under these conditions is encountered in the membranous urethra will yield after a few minutes of continued gentle pressure, aided if necessary by the instillation through the catheter of a two-per-cent. solution of cocaine. According to the tolerance of the inflamed and hypersensitive tissues, from a few minims to a dram or two of a warm solution of silver nitrate one-half to one grain to the ounce, are now slowly instilled into the bladder, the catheter withdrawn and the patient allowed to void the solution. In the majority of cases the relief that follows the temporary aggravation of the symptoms is surprising. The instillation may be repeated after forty-eight hours if the first gave relief and if the symptoms return; but if it did not give satisfactory relief, a solution of protargol, from one to eight per cent., may be tried instead of silver nitrate.

Two observations should be added here: (1) From the results obtained by the use of from one- to eight-per-cent. solutions of protargol in the subacute and chronic stages of urethrocystitis, it is fair to assume that the same solutions would be of benefit in the acute stage, thus avoiding the preliminary irritation of silver nitrate. As yet I have not had an opportunity to test the assumption. The beneficent effect of the one-per-cent. solution of protargol used as a hand-injection in acute gonorrheal anterior urethritis is not better manifested than in the distinctly infrequent occurrence of the severe grades of posterior urethritis and consequent urethrocystitis. (2) Irrigation of the bladder from the meatus with a warm solution of boric acid, borolyptol, potassium permanganate or mercuric bichloride in proper strength sometimes gives satisfactory relief when it can be performed; but to most patients with acute urethritis it is a distressingly painful procedure and hence should not be performed; in others, because the patient cannot relax his vesical sphincter, the irrigation cannot be performed. Moreover, the danger of causing epididymitis by such irrigation is great, especially if antecedent attacks of posterior urethritis have left the ejaculatory ducts rigid with inflammatory deposit, and, as a consequence, their mouths more or less patent. Finally, irrigation of the bladder from the meatus is dangerous under the conditions given, it having been demonstrated that rapid filling of the bladder to its point of toleration under pressure when tenesmus is present is very liable to drive some of the fluid into the ureters, thereby exposing them to infection either directly by contact or indirectly through the induced hyperemia.

The course of urethrocystitis and its prognosis are those of posterior urethritis. It tends to chronicity. Ulceration from this cause is rare.

Cystitis, meaning thereby acute general cystitis, occurs infrequently as a complication of gonorrheal posterior urethritis. The greater constitutional disturbance in the form of fever and the larger area of hypogastric pain and tenderness serve to differentiate it from urethrocystitis and to offer the few additional indications for purely medical treatment—the exhibition of antipyretics, as well as sedatives and anodynes, and the more liberal employment of fomentations with counterirritants.

The surgical treatment is that of urethrocystitis, slightly modified. When to resort to it must be determined by the symptoms. If possible it should be postponed until the subacute stage, but at whatever stage employed the decision as to the solution for instillation should be in favor of the milder, if not the mildest, for two reasons, first, that vesical congestion be not unwarrantably increased; second, that the instillations may be repeated in the form of small irrigations to wash away the accumulated pus and *débris* of the inflammatory process before a final instillation is made to be voided by the patient after the catheter has been withdrawn. The solution recommended is one-per-cent. protagol; it combines a maximum specific effect upon the gonococcus with a minimum of irritation. The solution must be introduced into the bladder very slowly and the quantity must be small—an ounce

or less. Here, as in urethrocystitis, forcible irrigation is overzealous treatment and is to be condemned on the grounds already given.

Ureteritis and pyelitis are so intimately interdependent and the symptoms of one so blend with those of the others that they must be considered as one. They are serious complications; by them the integrity of the kidney and the life of the patient are endangered. Hence proper treatment of the antecedent and associated cystitis has an important prophylactic value. Fortunately the complication is rare.

Like the bladder, the ureter and pelvis of the kidney, by reason of their squamous epithelium, present a barrier to gonococcus infection; it is highly probable that the soil must be prepared by an antecedent or coincident infection of another order before the gonococcus can flourish. Equally, like the bladder, anything causing congestion in the ureter predisposes to infection, as, for example, the presence of a calculus or an elbow or twist, as may occur with movable kidney. Associated with tuberculosis, a gonococcus invasion of these regions produces a very severe form of inflammation.

The treatment of ureteropyelitis is directed specifically against the local inflammation and against the occurrence of kidney congestion or hyperemia. Hence recumbency, fomentations, counterirritation and cupping, milk diet, diaphoresis and a mild degree of catharsis are imperatively indicated. Meanwhile the dose of urotropin, cystogen or salol, is diminished because of the possibly irritating effect upon the kidneys, while diuresis is continued to avoid any accumulation of thick pus which alone, by partially obstructing the flow of urine to the bladder, would become a potent cause of renal hyperemia through the pyonephrosis induced and possibly eventuate in pyelonephritis. The constitutional disturbances are treated symptomatically, and the cystitis or the urethrocystitis are not neglected. It would seem a provision of Nature that the inflammation tends to spend itself in the pelvis of the kidney instead of at once invading the kidney proper. Hence resolution is the rule in the recent cases, especially if the usual contributing causes—urethral stricture and cystitis—are relieved by judicious treatment.

If, by the well-recognized symptoms—chill, fever, pain, diminution of urine, and later a tumor—pyonephrosis is diagnosticated and the patient is obviously losing ground, drainage of the renal pelvis through a lumbar incision should be resorted to. If the operation is contra-indicated by any fact, gentle pressure over the kidney and along the ureter may be undertaken in the hope of overcoming the obstruction and so evacuating the pus by way of the ureter, or, aspiration may be performed. There is danger of rupturing the pyonephrosis by the former measure; aspiration rarely effects permanent relief.

The prognosis after drainage under these conditions is fairly good, provided pyelonephritis has not developed before the operation. The last-named condition calls for nephrectomy, provided the other kidney is present and normal, as offering the only chance of saving the patient's life. The details as to indications and contra-indications, however are beyond the scope of this paper.

Supposing the acute ureteropyelitis to have subsided without invasion of the kidney, and the chronic stage to have been reached, catheterism of the ureter to prevent stricture and for irrigation of the kidney pelvis may be thought necessary. On the other hand, in the face of a smoldering gonococcal inflammation, the traumatism and consequent congestion of catheterism may make that procedure a rash one. It will be safer to treat the ureteropyelitis by treating the now subacute or chronic cystitis or urethrocystitis by appropriate instillations and irrigations, and by diluents and appropriate medication. Upon their cure depends that of the ureteropyelitis eventually.

Funiculitis of gonorrheal origin is an inflammation of the whole spermatic cord by extension from the vas deferens as one of its component parts. It is not a common complication. Two forms are described, the simple or serous funiculitis—practically a diffuse hydrocele of the cord—and the phlegmonous funiculitis. Obviously peritonitis is possible from this source.

The treatment is suspension of all direct treatment of the urethra, anterior and posterior alike, recumbency with elevation of the hips, leeches, cold by means of an ice-bag or evaporating lotions, and a mild mercurial purge. If the cold is not well borne or later, if suppuration is inevitable, moist heat is to be substituted and the pus evacuated by incision. In the presence of marked edematous swelling without suppuration an incision may be necessary to relieve the tension and consequent pain. Whether suppuration has occurred or not, moist heat in the subacute and chronic stages will favor resolution. In addition mercury and iodide of potassium should be administered, because of their aid in causing the absorption of recent exudates, that every effort may be made to avoid occlusion of the vas deferens. If a patient will consent to go to bed as soon as pain or aching or a dragging sensation has developed in either or in both groins, it may be possible, by the application of cold to the affected groin and by supporting the testicle with a sling, to spare him the succeeding complication—epididymitis.

Epididymitis and epididymo-orchitis of gonorrheal origin usually are severer in both local and constitutional signs than those due to traumatism. In this discussion we may, for the sake of brevity, regard orchitis as a complication of epididymitis and deal with the latter alone. It constitutes the most familiar, if not the most common complication of acute gonorrheal posterior urethritis. This fact, together with the destructive effect it may have upon the man's virility, makes it most important.

As to treatment, to that of the first stage of

funiculitis is added immobilization of the inflamed epididymis. This is the cardinal point. The ordinary suspensory bandage does not suffice. The scrotum must be reflected upward until the testicles rest upon the pubes, and by means of a sling adjusted from a broad belt about the waist, they must be retained in that situation. The character of the application made to the scrotum over the affected epididymis is not of vital importance. Speaking generally, if the case is seen within the first twenty-four hours an ice-bag is indicated, and may be kept in position so long as it continues to give comfort. If the case is not seen within the early stage, and whenever the ice-bag does not afford comfort, moist heat should be employed. The "continuous poultice," as it may be called, is formed by surrounding the inflamed organ with a compress wrung out of hot water and covered with rubber tissue. An anodyne ointment, containing menthol and belladonna for example, may be similarly used. The evaporating and anodyne lotion of tinct. aconit., tinct. opii, liq. plumbi subacet. dil. and aqua may be preferred. As counterirritants, guaiacol and nitrate of silver, gr. 60 to the ounce, painted over the scrotum, may be employed at any period of the acute stage. The relatively new compound guaiacol-vasogen is similarly useful. In the declining stage, the "continuous poultice" in the form of compress or ointment covered in by rubber tissue should be worn and mercury and iodide of potassium should be exhibited for the reasons and the purpose mentioned under funiculitis. It may be necessary to continue this part of the treatment many weeks.

Suppuration is not as common in gonorrheal epididymitis as it is in that occurring in the course of catheter life. It requires incision and drainage.

The febrile movement and the pain of an acute epididymitis may make the administration of an antipyretic and analgesic desirable.

Acute prostatitis is a fairly frequent complication. It gives rise to constitutional symptoms that usually require active treatment, and to local pain that demands relief by anodyne suppositories or by morphine with atropine injected into the perineum. The urine is to be kept in quantity and quality, and instrumentation rigidly restricted, as in urethrocystitis and cystitis. Elevation of the hips and support of the testicles are important.

The local treatment as such is, at the outset, leeches applied to the perineum and to the margin of the anus, continuous cold to the perineum by means of an ice-bag, and intermittent cold directly to the prostate by means of a small rectal psychrophore. On the other hand, the effect of heat in relieving the urethrovesical spasm and in avoiding the tendency to it, may make it the part of good judgment to substitute poultices and hot rectal irrigations with normal salt solution. The rectal instruments chosen for these cases should be small, and if by their pressure they cause pain or an aggravation of the symptoms, their use should be discontinued.

Meanwhile, by digital examination at regular intervals, signs of suppuration are sought in the gland. It occurs occasionally. The detection of an abscess in the prostate is not always easy, especially if the focus be deep-seated. Consequently, it not infrequently happens that before fluctuation becomes manifest to the finger a sudden gush of pus from the urethra during an effort to urinate marks the rupture of a follicular abscess. Retention of urine in the course of acute prostatitis makes it highly probable that an abscess is pointing toward the urethra or the bladder. This secondary complication necessitates using the catheter, the very introduction of which is the means often of rupturing the abscess.

When fluctuation is discovered, the abscess should be evacuated and drained through a transverse perineal incision. It should be noted that the pus first escaping through such an incision may come from a periprostatic abscess, and that unless this cavity is explored, and the prostate palpated by the finger, an abscess in one or the other lobe may be overlooked. If there is any doubt, an aspirating-needle should be passed along the finger as a guide and pushed onward into the suspected lobe. If pus is drawn, an opening is made along the course of the needle and drainage established.

The treatment of the subacute and chronic stages of prostatitis, whether the acute stage ended in resolution or in suppuration, can be given only the briefest summary in this paper. Digital massage of the gland, hot rectal irrigations, bladder irrigations, and instillations into it and the deep urethra, form the outlines.

Acute seminal vesiculitis about equals acute prostatitis in occurrence. With epididymitis and prostatitis it forms a trio of interdependents, any one or two of which, however, may exist without the others. The treatment is that of acute prostatitis in all respects with, in addition, appropriate medication to relieve the priapism—a somewhat pathognomonic and very annoying symptom of acute inflammation of the vesicles.

Suppuration within the vesicle very rarely requires surgical intervention; the pus finds exit through the ejaculatory duct. If, however, a perivesiculitis goes on to suppuration, the abscess must be evacuated. The pus can be reached through a transverse, a curved or a U-shaped perineal incision. The necessary dissection is facilitated by having the patient in the knee-chest position with the thighs astride the table as recently recommended by Dr. Fuller.

The treatment of subacute and chronic vesiculitis also is that of the corresponding stages of prostatitis. It should be noted that when to begin the massage, whether to continue it, and how often to repeat it, depend upon the condition of the inflamed organ and the effect produced.

Gonorrheal rheumatism, as representative of the general or systemic complications, may occur at any time in the course of either anterior or posterior urethritis. Usually, however, it occurs

later, rather than earlier, and therefore is associated with the latter.

Internal medication is directed chiefly against the constitutional disturbance. Though antirheumatics are of little avail, they should be tried. Oil of gaultheria would seem to be the most reliable. Iodoform until headache develops, or the odor is noted in the feces has been advised. A German observer (Ruheman) has used protargol in three-grain pills, three to four times daily, with apparent good results.

The local treatment is all important. Immobilization by a posterior splint or a fenestrated plaster-of-Paris dressing; counterirritation and blistering, by the nitrate-of-silver stick, or the Paquelin cautery, for example, and cold by means of the ice-bag are indicated in the early stage. Later, the ice-bag is replaced with poultices and they in turn with compression, if effusion into the joint has taken place, to hasten the absorption of the fluid. In this, iodide of potassium internally, may assist. Well on in the subacute stage daily massage and tentative passive motion are begun.

In the event of severe suppuration within the joint tapping and irrigation with a solution of carbolic acid or mercuric bichloride under strictest surgical precautions are indicated. Suppuration in the peri-arthritic tissues calls for incision and drainage of the same. In the severest cases of suppuration within the joint, arthrotomy, irrigation and drainage may become necessary. After any one of these operations, follow in turn immobilization, compression, massage and passive motion. The treatment of the urethritis, meanwhile, should be active, yet conservative, as instrumentation in acute urethritis often seems to precipitate a gonorrheal rheumatism in a predisposed patient. In proportion as the infection is arrested at its source the arthritic manifestations subside. Consistently the general health should receive attention, as most sufferers from gonorrheal rheumatism are anemic and have not vitality enough to resist infection.

MEDICAL PROGRESS.

Toxemia of Pregnancy.—It is still very uncertain what is the true cause of systemic poisoning which occurs during pregnancy, but it is probable that it depends upon many factors. The warning sign, however, which points to danger is, according to S. MARX (*Med. Rec.*, Apr. 20, 1901) the diminution in the amount of urea excreted. Women may go to term with albuminuria and casts without symptoms of toxemia, and in the most malignant cases there are neither casts nor albumin found. The excretion of urea is the important sign to be watched and regular examinations should be made upon twenty-four-hour specimens to determine the ability of the system to excrete the poisonous principles. The essential point in treating a uremic condition lies in the stimulation of all the emunctories. Calomel, jalap, elaterium or the salines work best upon the bowels, while the skin is best stimulated by hot packs, sweatings or mild diaphoretics. Pilocarpine is not recommended. To increase the function of the kidneys, a milk diet, an abundance of water to drink and hot rectal or colon irrigations, quarts being used at a time, seem to be the most efficacious. When the heart is overacting and the pulse large and bounding venesection is frequently of great value. The vasodilators are the most valuable drugs, nitroglycerin, chloral and small doses of opium. Sparteine and caffeine are useful cardiac stimulants. Digitalis is frequently too irritant for the kidneys.

Malignant Endocarditis.—Three cases of this disease are reported by A. E. ROUSSEL (*Med. Rec.*, Apr. 20, 1901) one of which followed an attack of measles, another developed during a convalescence from typhoid and the third succeeded closely upon a miscarriage of twins and finally resulted in recovery. Only three instances are noted in literature where malignant endocarditis was secondary to measles and yet the reported case seems to be an undoubted illustration. In Osler's collection only four patients under ten years developed malignant endocarditis during or succeeding an attack of typhoid. One of the reported cases was that of a child of nine years of age who had all the characteristic symptoms and signs of that condition. The leucocytes also rose to 50,000 which seldom occurs in these conditions. The third case might be considered of doubtful diagnosis on account of the recovery, but the patients manifested all the usual symptoms. She had a large liver and spleen, ran an irregular temperature with occasional chills and sweats, had multiple abscesses in various parts of the body and cultures from the blood showed streptococci. Later in the illness she developed systolic murmurs over the apex and base, had considerable pain in the precordial region and the heart's action because tumultuous and diffuse. It is now believed that the simple endocarditis is usually infective, the difference between it and the malignant form depending upon the virulence of the germ. The staphylococcus is the more fulminating form, the pneumococcus and streptococcus infection being long drawn out.

Diagnosis of Ectopic Gestation.—The symptoms which should lead to a recognition of the above condition may be divided into ordinary and extraordinary. A. F. CURRIER (*N. Y. Med. Jour.*, April 20, 1901) mentions among the first class all the symptoms and signs which are present during the early weeks of a normal pregnancy: Points in the history which may lead to the suspicion of an ectopic gestation are retroflexion of the uterus, previous sterility, disease or dislocation of the Fallopian tubes, a bicornate uterus or a previous ectopic gestation. The most important of the extraordinary signs is hemorrhage. This is seldom external or manifest. A fetal sac at the fimbriated end of the tube seldom progresses to the end of the first month without rupture. When within the tube abortion usually

occurs between the sixth and twelfth weeks. The weakness of collapse, the flickering pulse, the pinched face and the shallow breathing is most significant. Next in importance is pain. It is always present, usually paroxyzmal, sharp and darting and the thigh is commonly flexed upon the abdomen. Whether due to the stretching or rupture of the peritoneum or to a localized peritonitis it is not known. The presence of a tumor made out most easily by rectal bimanual examination under ether, if necessary, is the third diagnostic point. These three symptoms—hemorrhage, pain and tumor, are the most important of the extraordinary symptoms and are the most constant. An early diagnosis is usually necessary to a successful termination of the case by surgical interference.

Cystinuria.—Only seventy-five cases of this malady have been found in literature and no recoveries reported. A fermenting organism is supposed to produce cystine and intestinal digestion is usually the function attended to. J. Reid (*N. Y. Med. Jour.*, Apr. 20, 1901) had a patient suffering from painful micturition in whose urine cystine was present. An ulcer in the anterior urethra was finally healed by local application of calomel and by the internal use of gray powder, and later, by the use of quinine and tannic-acid powders the cystine entirely disappeared.

Acute Spinal Ataxia.—This condition, coming on in a few days or weeks, is characterized by a marked ataxia of the lower extremities with some temporary or minor sensory disturbances and is usually classified as an acute cerebral or cerebellar ataxia, an acute peripheral ataxia due to multiple neuritis or an acute form of tabes dorsalis. C. L. Dana (*N. Y. Med. Jour.*, April 20, 1901) reports four cases without autopsies and advances the theory that they are due to senile arterial changes or to syphilitic lesion of the posterior blood-vessels of the spinal cord, causing either a blocking or hemorrhage with the usual reactive process. All cases showed a marked ataxia. They could not walk except in the characteristic ataxic manner. There was some disturbance of cutaneous sensations, but no loss of pain or thermic sense. The knee-jerks were absent in two cases, slightly exaggerated in one. There was some paresis, but no wasting and no reaction of degeneration. The bladder and rectum were slightly disturbed. The patients suffered no pain either at the onset or later. The prognosis seems to be very good for the improvement is usually decided though rather slow. The acute onset, the age of the patients, usually above fifty, the history of lues, and the characteristic symptoms, all make it practically certain that it is a vascular disorder involving either hemorrhage or softening. The absence of pain or fever and the rapid recovery show that the process is not an inflammatory or degenerative one.

Obstetric Hemorrhage.—The antepartum hemorrhages suggest miscarriage, placenta previa, premature separation of placenta, ectopic gestation, rupture of uterus, or menstruation during gestation, yet, writes J. Clifton Edgar (*Amer. Gyn. and Obstet. Jour.*, Apr., 1901) they may be due to the fever and local hyperemia of the exanthemata as variola, scarlatina, and measles, of venous obstruction due to heart, liver and visceral conditions, of hematosalpinx, sarcoma, fibroma, polypus, and epithelioma. Less frequently the hemorrhage comes from the urethra or other extra-uterine source. The most important of all is the bleeding indicative of a threatened or inevitable abortion. Severe hemorrhage from low implantation of the placenta is much more common than generally believed. The hemorrhages of labor are due to premature separation of the placenta, ruptures of uterus or cervix, and fibroids, malignant disease, or varicose veins. In the third stage uterine inertia is the most important factor, next, lacerations of the genital tract, insufficient contraction of the lower uterine segment, partial or complete inversion, or fibroids or cancer. Puerperal hemorrhages are due to mental emotions, disturbances of the circulation, malaria, albuminuria, sepsis, and the acute infectious diseases. Also locally to retained clots, placenta, or membranes, a secondary placenta, distended bladder or rectum, retroflexion, inversion, fibroid and polypoid tumors, cervical lacerations, malignant disease, and subinvolution. Pelvic hyperemia may be induced by assuming the upright position too soon after delivery or by too early sexual intercourse.

Renal Tuberculosis.—H. M. Kinghorn (*Montreal Med. Journal*, Mch., 1901) finds that the general symptoms are often lacking at the onset, but later there may be loss of appetite and weight, perhaps some night-sweats, and especially fever with evening rise. Polyuria is one of the first indications, and frequency of micturition, equally marked at night, is suspicious. At any time there may be a brisk emission of considerable pus; or blood in clots or streaks may appear. Blood not clotted is intimately mixed with the urine, and the hematuris may be intermittent, lasting for a few days at a time. The bacilli are differentiated with such difficulty from the smegma bacillus even with acid alcohol, that guinea-pig inoculation is the method of choice for diagnosis. The stain used in Trudeau's laboratory is carbol-fuchsin, which when washed and dried is decolorized with 25-per-cent. nitric acid, washed and dried, and placed for two minutes in 95-per-cent. alcohol. Tumor in the kidney region is a late symptom but should be looked for. Pain depends on involvement of pelvis or ureter, though if the kidney parenchyma is involved alone there may be a dragging sensation. As a rule the pain is uninfluenced by motion, but is quieted by the dorsal decubitis. It may be aggravated by meals, or a blow or cold, but chiefly before the monthly period. It may be sharp, simulating stone, possibly from the excretion of purulent lumps or phosphatic concretions, or from renal congestion.

Mediastinal Tumors and Aortic Aneurisms.—The differential diagnosis between both conditions will always be a difficult chapter in medicine, since pressure symptoms form the dominant features in both, yet H. Hampelin (*Zeitschft. f. kin. Med.*, Vol. 42, No. 304) gives a few valuable points, based upon an observation of 200 cases. Stenosis of the trachea points strongly toward aneurism of the arch or trunk of the aorta. Bronchial stenosis, on the other hand, occurs equally often in both conditions and betrays their presence more on physical examination of the lungs than by dyspnea. Symptoms of esophageal stenosis generally enable an exclusion of mediastinal disease and point more to changes of the esophagus itself, such as stricture and carcinoma. Recurrent paralysis is generally a symptom of aneurism. In doubtful cases a recurrent paralysis occurring in advanced age with cachexia will speak for tumor, while if occurring earlier, with syphilitic antecedents, aneurism is the more likely of the two. Premonitory pulmonary hemorrhages turn the evidence in favor of aneurism. Finally Oliver's symptoms and the X-rays may be resorted to, though the latter rarely give much help.

A Case of Acromegaly.—An interesting case in which the symptoms of acromegaly were well-developed, came under the care of M. A. Trachtenberg (*Zeitschrift. f. klin. Med.*, Vol. 42, No. 3 and 4). The patient, a woman aged thirty-one years, showed the typical increase in size of hands, feet and face, especially the lower jaw, where the nose was broad and thick, the lower lip indurated and everted, the tongue enormous and the uvula elongated. Among the typical symptoms may be mentioned thickening of sternum and ribs, a slight kyphosis, absence of menstruation and abdominal type of breathing, as well as dulness over manubrium, exophthalmos, temporal hemiopia, polyuria, general weakness and failure of memory. In discussing the disease the author ascribes the dulness over the sternum to thickening of that bone and does not think it indicative of hypertrophy or persistence of the thymus since postmortem examinations have often shown this to be absent and since, in his opinion, the disease is purely pituitary in origin, though it is by no means clear whether dependent on increased or diminished activity of that gland. Contrary to the observation of most other writers, no signs of hypertrophied left ventricle could be detected.

Uterine Displacement With Adhesions.—When F. H. Davenport (*Amer. Gyn. and Obstet. Jour.*, Apr., 1901) finds the uterus tipped backward, immovable, and with ovary and tube matted to it with plastic material, he places the patient in Sims' position and packs the vagina firmly with pledgets of cotton soaked in glycerin. The upper two-thirds of the vagina must be filled, for it is pressure that is wanted. The first packing must not be too forcible, as the pelvis may be sensitive. The treatment is repeated every two or three days, and after two or three packings the uterus is drawn down by a double hook in the anterior lip, and lifted by the fingers. If bands are felt, they may be massaged and lightly stretched. Definite results should show inside of about three weeks, and the softening and disappearance of exudates, and the extent to which the uterus has been replaced is surprising. At the approach of menstruation, a well-fitting pessary should be applied to be worn during the period. In obstinate cases the treatment may be prolonged for a second month. If the adhesions are very dense and the patient's sufferings are marked so that relief is imperative, removal of the appendages and amputation of the uterus should be performed. The breaking up of adhesions with ventral fixation gives only temporary relief. As such patients are usually sterile the question of pregnancy need not be taken into account.

Endocarditis.—In acute endocarditis F. L. Newman (*Physician and Surgeon*, Mch., 1901) specifies four weeks as the shortest time for rest in bed and careful nursing. At this time in the sthenic cases tincture of aconite, 4 or 5 drops every three or four hours, will relieve an overacting heart, and Dover's powder or morphine will control pain. However, the majority of cases are asthenic and require digitalis, strychnine, ammonia, or ether. Usually, however, digitalis is not necessary till the acute process is passing into valvular disease. The local application of heat or cold, or a large belladonna plaster to exert pressure is often very grateful to the patient. In chronic endocarditis whatever the lesion, when there is lack of compensation with venous congestion the treatment is that of cardiac dilatation. Previous to this no medicine is needed, but care in eating, and avoidance of overexertion. At first indication of heart-failure put patient to bed, have meals light, small and several times a day, and avoid large quantities of fluid as it increases too suddenly the contents of the blood-vessels. In aortic regurgitation digitalis by lengthening the diastole allows more blood to run back into the ventricle and so may produce anemia of the brain and even fatal syncope. Yet where the dilatation is the principal lesion there is no drug so tonic to the heart-muscle as digitalis. If the heart does not respond in a few days, compensation is probably gone forever. Strophanthus is next in importance; strychnine is valuable, and caffeine though uncertain in its action on the heart, is valuable for its diuretic powers. Nitroglycerin has no action on the heart, but decreases the resistance to its systole. The symptoms must be met as they arise. For palpitation there is the ice-bag, belladonna plaster, or hypodermic of morphine; for dyspnea, nitroglycerin; for enlarged liver, calomel or sodium phosphate; for bronchitis, codeine, morphine, heroin, or hydrocyanic acid. The edema should be relieved by punctures with a large-sized needle under aseptic precautions, and fluid in the pleural cavities should be removed without delay.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MAY 18, 1901.

THE LUNACY COMMISSION.

IT has been said of Governor Odell that he has that most potent of faculties, "the seeing eye," and that he is able to divine by his knowledge of character whom to choose among the multitude to fill the positions of trust in the State.

Certainly no better instance of his penetration could be shown than in his appointment of Dr. Frederick Peterson of New York to the Presidency of the State Lunacy Commission, to succeed Dr. Wise. The success of every enterprise that Dr. Peterson has put through, in spite of the demands of a large consultant practice, has proved him a man eminently able to lead and to organize. His efforts that led to the establishment of Craig Colony for Epileptics afforded a practical illustration of the grasp of principle and detail that he possessed in adapting the bounty of the State to this branch of the dependent poor.

It is rare to find a scientific man who is an authority on his subject and at the same time competent and willing to apply his knowledge to public machinery. The acceptance of such an office by a man whose reputation is as well-known as Dr. Peterson's cannot be regarded otherwise than as a public spirited move, for although he consented to serve on the condition that the office should not interfere with his practice, nevertheless the shouldering of so much responsibility and the expenditure of the necessary time is much for a man to give to the service of his State.

Every alienist in the State will feel that Dr. Peterson's appointment will bring a fresh stimulus to the work in psychiatry, and that the tendency to do something for the insane, apart from simple custodial care, will grow.

To the citizens of New York City who have been obliged to take the treatment that Bellevue offered them, the possibility of a Psychopathic Hospital comes like a prospect of relief from the very inadequate and inefficient provision made for the acutely insane in this city. The time is ripe for making advances in the administration of the city's insane asylums, and for doing original research work with the vast amount of clinical and pathological material at hand.

Everything is ready for a leader, and Dr. Peterson, who knows men and hospitals, here and abroad, who has directed laboratories, conducted clinics, and introduced a wholly original method of caring for dependents into the State, is just the man to introduce an era of brilliant work in psychiatry, and we congratulate Governor Odell for having put the right man in the right place.

IMMUNITY TO TYPHOID FEVER.

THE immunity to certain acute infectious diseases which is conferred by one attack has naturally led many to expect the same after typhoid fever. Kanthack (Allbutt's System of Medicine) states that recovery from typhoid fever implies an immunity which lasts for years. Dreschfeld, in the same work, mentions the existence of a natural immunity in some persons and says that acquired immunity is a well established fact. He cites as an example the fact that in over two thousand cases in the Hamburg General Hospital only fourteen were affected twice and one three times.

The Widal reaction is now usually considered as chiefly of confirmatory value, although many believe it to be of actual diagnostic significance in spite of the frequent tardiness of its appearance, its occasional absence in pronounced cases of typhoid, and its occurrence in other diseases. Grüber believed that a strong Widal reaction indicated the establishment of a corre-

sponding immunity to subsequent attacks. If this idea is correct and the presence of the agglutinating power of the blood serum is indicative of such immunity it must be conceded that the duration of the immunity is most uncertain, as the reaction sometimes fails early in convalescence and on the other hand has been observed after eight and twelve years.

That immunity is not always conferred by a first attack is illustrated by two cases reported by Nicol (*Lancet*, April 6). The first had a severe form of typhoid with hemorrhages in May, 1900. The Widal reaction was obtained. In November, 1900, he suffered from the disease a second time. It was moderately severe and of rather long duration. The Widal's reaction was again found. The second patient's first attack was in April, 1900, and the second in September, 1900, both of moderate severity. This does not necessarily show a second exposure to the disease. That the typhoid bacilli may live in the body without giving symptoms of enteric fever has been demonstrated by their frequent occurrence in the gall-bladder some time after the attack. In suppurative cholecystitis some months after convalescence from typhoid, a pure culture of the bacillus has been found. To what extent immunity has been conferred in such a case is doubtful.

The bacteria continue to live in the body, yet fail to give rise to the specific lesions which they usually cause. A second attack may be a relapse, that is, a return of the attack during convalescence, or a recurrence months or years later. The short interval between the attacks in Nicol's cases would suggest that the bacilli had remained in the body and their activity had been reawakened. If a durable immunity is conferred by one attack this should not occur. One would also expect the degree and duration of immunity to correspond with the severity of the attack.

The question is important in relation to the possibility of securing artificial immunity by anti-typhoid inoculations of the dead bacteria and their toxins. Nicol states that many of the soldiers who suffered from typhoid in South Africa had been inoculated in this way while en route thither by ship. Wright, on the other hand, presented statistics of 11,295 British troops in India and South Africa, 2,835 of whom were inoculated. Two and five-tenths of those not inoculated and only .95 per cent. of those inoculated were attacked by typhoid. His statistics of the besieged garrison at Ladysmith show that 14.1 per cent. of the 10,529 not inoculated suffered from the disease, as against 2.05 per cent. of the 1,705 who were inoculated.

Comparison of the results obtained by many observers seem to show that, while immunity is not constant after one attack of typhoid, it appears to be established for an extremely variable period in many cases. The results obtained among the British troops in South Africa and India apparently justify the idea that inoculation confers immunity frequently enough and of sufficient duration to lead to further use of this procedure, at least in cases where large bodies of men are exposed to the disease under unfavorable circumstances.

THE PATHOLOGY AND TREATMENT OF PERNICIOUS ANEMIA.

That pernicious anemia is not necessarily a primary affection is a conception now held by many students of blood pathology. In many cases its secondary character needs no particular demonstration, but there has seemed to remain, as a nosological entity, the type of progressive pernicious anemia, originally described by Addison.

That this type of the affection might be due to some form of gastro-intestinal infection is the theory advocated by Dr. William Hunter, and recently set forth in a striking manner at the Medico-Chirurgical Society of London.

He concludes that a micro-organism, as yet not definitely isolated, brings about by means of the gastro-intestinal canal a specific infection which leads to the definite and characteristic symptoms of the affection. Oral, gastric and intestinal sepsis is the fundamental note of his theory and it is this sepsis which brings about the hemolysis, and the intermittent blood changes with the peculiar anemia, lemon color, dyspnea, hemorrhages and palpitation. Periodic disturbances of the viscera themselves are but indices of the local results of sepsis, and occasional toxemic effects marked by general nervous prostration, fever, sweating, ataxia and nerve storms are the consequences of a generalized infection.

Adopting this hypothesis he has been enabled to treat successfully some patients, one of whom was presented to the society as cured. The line of treatment is rigid antisepsis. Diseased teeth, infected buccal membranes and lingual lesions are to be energetically attacked. Gastro-intestinal lavage and medicinal antisepsis should be practised. In addition to the usual constitutional treatment with arsenic Dr. Hunter advocated the

use of the antistreptococcic serum. This was not directed against any known coccus, as such are not known to be hemolytic, but as a general measure.

Should further observation and treatment confirm Dr. Hunter's views, one more of the hitherto incurable affections may be said to have been conquered.

DOCTOR CHARLES RICE.

In the death of Dr. Charles Rice of New York the medical practitioners of this country have suffered a loss greater than they are perhaps able to appreciate because few of them in the hurry of their professional life pause to think of the source from which the materials of their art are derived.

The physician who has had little or no training in pharmacy takes the preparations that are given him, never asking any of the thousand and one questions that may arise regarding their purity nor their standardization, etc.

He remembers vaguely that there is such a standard as the *United States Pharmacopœia;* but of its character and its formation, its objects, its scope and its fundamental value to his daily work he rarely stops to think.

The *United States Pharmacopœia,* to-day, stands in the front rank of works of its kind as the last word on all matters pertaining to the preparation of remedies. The position that it occupies is due in large part to the careful, conscientious and learned chemist who has just relinquished his life's work.

Of the man we could say much, his work has already spoken for him. He has been a power in the pharmaceutical world not only by his great knowledge but by his personal efforts. He raised the standard of the pharmaceutical organizations throughout the country and established a feeling of confidence between the physician and the pharmacist which had not existed until the reliability of the *United States Pharmacopœia* came to be an accepted fact in both professions.

He was a man of versatile powers, a scholar and a scientist, one who always grasped the kernel of truth.

ECHOES AND NEWS.

NEW YORK.

Mount Sinai Hospital Cornerstone.—Gov. Odell, President Seth Low, Randolph Guggenheimer, Edward Lauterbach, and Dr. A. Jacobi will be the speakers at the laying of the cornerstone of the new Mount Sinai Hospital, at Fifth Avenue and One Hundredth Street, which will take place on May 22d.

Appointment of Dr. Fischer.—Dr. Louis Fischer has been appointed a Visiting Physician to the Willard Parker and Reception Hospitals.

Tuberculosis Congress.—The second annual meeting of the American Congress of Tuberculosis met this week at the Hotel Majestic. Delegates from the different States were present and many interesting papers were read. Dr. Clark Bell opened the Congress. Dr. Pryor of Buffalo said that 14,000 die of tuberculosis in this State every year, and 74 per cent. of these he believes might be saved if a correct diagnosis were made in the incipient stages and appropriate treatment instituted. The rich can go to sanatoria but the poor must die unless the State makes some provision for them. This New York State was about to do in the opening of the Adirondack Sanitarium.

PHILADELPHIA.

University of Pennsylvania.—Dr. Thomas R. Neilson has been elected Clinical Assistant Professor of Genito-urinary Diseases. Dr. Neilson has been at different periods Assistant Demonstrator of Anatomy and of Surgery at the university and also Professor of Genito-urinary Surgery in the Philadelphia Polyclinic.

New Pest House at Marcus Hook.—An emergency house capable of accommodating 500 patients has been completed at the State Quarantine Station at Marcus Hook. A new crematory has also been added to the equipment of the station. This station is said to be the second oldest in the world, having been begun in 1746.

Jefferson Commencement.—The Seventy-seventh Annual Commencement of the Jefferson Medical College was held in the Academy of Music May 15. A class of 142 was graduated. The address to the graduates was delivered by Professor W. W. Keen.

Lessons of a Decade in Hydrotherapy.—An address on the above subject was delivered at the County Medical Society May 8, by Dr. Simon Baruch of New York. Dr. Baruch said that the medical profession had been backward in adopting the use of cold water because of the erroneous idea that it produced shock. On the contrary, it produces the opposite effect when judiciously used. Water is used only for the purpose of conveying temperature. The desired effect of the use of cold water is the enhancement of the resisting powers of the individual. If a typhoid patient's teeth chatter while he is in the bath, the bath should be stopped. If he only shivers continue the bath, and increase friction. In treating insomnia by the use of hydrotherapy, warm water dilates the vessels and thus produces the desired ef-

fect. But if the patient gets out into the cooler air this effect is counteracted and the patient is wakened. To avoid this effect the patient should be wrapped in a warm sheet and blankets and then placed between warm sheets with hot water bottles surrounding him. The effect of the bath is kept up and sleep comes.

The Diuretic Effect of Water.—Dr. Baruch said it was a mistake to believe that the diuretic effect of water was due to the flushing of the kidneys and for that reason giving large quantities of liquids. Cold water acts in the stomach as it does upon the skin, causing a contraction and then a dilatation of the vessels. This stimulates the nerves, respiration, and the systole of the heart. These things bring about diuresis. Hence the giving of one or two ounces of water every 2 hours at a temperature of 40° F., will produce more diuresis than will a half-pint given less often.

One Hundred and Fiftieth Anniversary of the Pennsylvania Hospital.—The commemorative exercises celebrating the one hundred and fiftieth anniversary of the founding of "The Mother of American Hospitals" were held in the new Assembly Room of the hospital May 11. Benjamin H. Shoemaker, President of the Board of Managers, presided and after a short address of welcome introduced the orator of the day, John B. Garrett, one of the managers. The audience included many of the physicians of Philadelphia and numerous representatives of foreign medical and scientific societies. Mr. Garrett's address was almost wholly historical in character and traced the development of this beneficent institution from its inception to its present greatness. Benjamin Franklin is generally credited with being the founder of the hospital but disclaims that honor in his autobiography. However, he was largely responsible for the furthering of the plans of Dr. Thomas Bond in regard to the institution. The petition to the Assembly for help contained neither Franklin's nor Bond's signature but was in the handwriting of the former. That document contained a plea for the insane which was far beyond the spirit of the times and recognized lunacy as a disease forty years before it was so recognized in England or France. The wisdom of the charter granted is shown by the fact that it has never needed changing except to widen the limits of the property. May 11, 1751, the act incorporating the "Contributors to the Pennsylvania Hospital" was signed by Governor Hamilton. In August a temporary hospital was secured. In 1754 part of the present site was secured and in 1767 the balance of the 4.3 acres was added. The corner-stone of the present building was laid in 1755 and the patients removed from the temporary quarters the following year. Nov. 26, 1766, Dr. Thomas Bond gave the first clinical lecture in the hospital, this marking the beginning of systematic medical teaching on this continent.

The establishment of a separate department for the insane marked an epoch in the history of the hospital. A partial separation of the insane from other patients had been attempted in 1825 but the lack of quarters hindered the movement. A tract of 101 acres of land in West Philadelphia was secured in 1835, buildings erected, and in 1841 the insane patients were removed to the new quarters. These have been enlarged, the sexes placed in separate buildings and grounds, gymnasiums, and natatoriums, etc., erected since. This part of the hospital now has accommodations for 270 female and 250 male patients and during its 60 years' existence has cost upward of eight millions of dollars. The hospital proper has been extended and remodeled until it is now one of the most complete institutions of its kind in the world. The medical and surgical wards are in separate buildings, there are two nurses' houses, the dispensary is in a detached building across the street, a mechanical and chemical water filter of 250,000 gallons daily capacity is in use, a garbage incinerator has been erected, a laboratory of clinical medicine erected and endowed, and various other improvements made. All this has been done without State or municipal aid for over a century. The Pennsylvania Hospital is an institution of which Philadelphia is justly proud because of its history, its freedom from political influence, and the character of its work.

Woman's Medical College.—At the Forty-ninth Annual Commencement held May 16, a class of 37 was graduated. The address to the graduates was delivered by Dr. Elizabeth R. Bundy, adjunct Professor of Anatomy. Dr. Talcott Williams also gave an address.

CHICAGO.

Appointment of Dr. Webster.—Dr. George W. Webster has been appointed as member of the State Board of Health to succeed Dr. M. Meyerowitz, who has resigned.

Hospital for Employees.—A hospital for employees and for the residents of the vicinity is to be constructed at a cost of $50,000 at Judd Street and Twelfth Place by the Crane Company.

Watering and Sprinkling of Streets.—The economy of water for public uses is said to be peculiar to Chicago. With the most abundant supply of any large city, upward of 190 gallons daily for every man, woman and child, against an average of 118 for other large American cities and less than 40 for European cities, there are no fountains to wash and cool the air nor running streams in the gutters to catch the dust from street and sidewalk. According to the Health Department, it is little wonder that catarrh is universal and dust diseases more prevalent in Chicago than elsewhere. The proposition to flush the streets into the sewers after they have been swept, says the Health

Department, should be carried into effect forthwith as a sanitary measure of the first importance.

Opening of New Hospital.—The formal opening of the Hospital of the Chicago Eye, Ear, Nose and Throat College, the first institution of its kind in Chicago, took place May 11th. The hospital is situated at the College, 206 Washington St., and occupies one floor. One notable feature is the establishment of a number of free beds where patients are received and attended by a corps of physicians and nurses free of charge.

Decoration for Dr. Fenger.—Dr. Christian Fenger has just received the Cross of Dannebrog from King Christian IX. of Denmark, in recognition of his contribution to surgical knowledge. The decoration consists of a gold and enamel cross, with four royal golden crowns set between the arms. On its face it bears the inscription "God and the King."

Report of Special Committee on Investigation of Cook County Hospital.—Appointment of a new warden and many radical changes in the management of the Cook County Hospital are recommended in the report of the special investigating committee. The recommendation for the removal of Warden Graham was a surprise to those who had followed the investigation. No serious charges are made against his management, but in view of the political influence shown to be back of his appointment the members of the committee decided that another man, pledged to stamp out partisan politics and personal favoritism, should be selected by the county board. Another important recommendation provides for the selection of a medical director. It is declared further that permanent improvement in the condition at the hospital is not possible without thorough reorganization of the entire working force. These conclusions are generally favored by the members of the county board, and except for Graham's removal, which may meet with opposition, the suggestions of the committee are certain to be acted upon.

In discussing the work of the internes, the manner of their selection and their duties, the committee finds nothing to suggest. The medical staff, however, comes in for mild criticism because of the lack of system prevailing. It is recommended that attending physicians visit the hospital every day. The appointment of a medical director is desired, not to superintend the actual treatment of cases, but to see that the complicated machinery of the staff organization is working effectively. To facilitate the work of the medical staff the committee suggests that a medical board consisting of the director and one representative from each of the three schools of medicine be selected by the staff. Such a central authority over the entire staff, it is believed, would improve the service.

GENERAL.

American Medical Editors' Association.—The annual business meeting of the American Medical Editors' Association will convene in the library rooms of the Ramsey County Medical Society, Lowry Arcade building, St. Paul, at 2.30 P. M., Monday, June 3d. The Lowry Arcade building is situated in St. Peter street, between Fourth and Fifth.

Dr. Javal's Blindness.—At a recent meeting of the Académie de Médecine in Paris, M. Javal, the oculist, who was operated on a year ago for glaucoma and is now totally blind, presented an apparatus of his own invention to facilitate writing by the blind.

Dr. Matthews to Go to Chicago.—Dr. Harper announces that Dr. A. P. Matthews, the instructor in physiological chemistry of the Harvard Medical School, has accepted a place on the faculty of the Medical School of the University of Chicago.

Damages for Death at Telephone.—The Supreme Court of Vermont recently held that a telephone company was responsible for damages in the case of a physician who was killed by lightning while sitting in his library reading under a telephone instrument owned by the company.

Lepers' Home in Louisiana.—The citizens of Jefferson and St. Charles parishes for seven miles around the Gustine plantation, just bought for the Lepers' Home, met in mass meeting last week and adopted resolutions asking that the Lepers' Home be not established in a thickly settled neighborhood. The meeting was presided over by State Senator Brady.

Trolley Ambulances Planned.—It is reported that the Brooklyn Rapid Transit Company will provide a receiving domitory, with cots, medicines and the best medical attendants, for the immediate aid of persons injured on the lines of the company. The plan is to fit up an unused building at Fifty-second street and First avenue, on the same lines as the ordinary emergency hospital and also to follow the idea adopted by the New York Central Railroad at Buffalo. Everything that pertains to a well-equipped hospital will be placed in the building and an ambulance service by trolley will be provided.

Overcrowding in the Profession.—Statistics of the country relating to physicians indicate the possibility, if not the actuality, of overcrowding in the medical profession. It was found in the census year that there was one registered physician to every 655 people in the United States. That the number is in excess of the need is evidenced by a comparison with Germany, where, in 1898, there was only one physician to each 2,114 inhabitants, or relatively about one-third as many as in the United States. The doctors are more plentiful proportionately in some States than in others.

Thus, in California there was one physician to each 416 inhabitants, and in North Carolina one for each 1,189 of population. Even in states geographically connected and similar as to conditions there is wide disparity in the relative number of doctors. Thus, Michigan had one doctor to each 570 people, but in Wisconsin there were 936 inhabitants to each doctor, and in Minnesota one doctor to 1,004 people. Massachusetts has proportionately more doctors than are to be found in Connecticut and Rhode Island. The proportion in New Hampshire and Maine is much the same as it is in the Bay State, but Vermont finds employment relatively for a considerably larger number of medical men.

Mississippi Valley Medical Association.—It is announced that the dates of the next meeting of the Mississippi Valley Medical Association have been changed from the 10th, 11th, and 12th of September to the 12th, 13th, and 14th of September. This change has been made necessary because the dates first selected conflicted with another large Association meeting at the same place. The meeting is to be held at the Hotel Victory, Put-in-Bay Island, Lake Erie, O., and the low rate of one cent a mile for the round trip will be in effect for the meeting. Tickets will be on sale as late as September 12th, good returning without extension until September 15th. By depositing tickets with the Joint Agent at Cleveland and paying 50 cts. the date can be extended until October 8th. This gives members an opportunity of visiting the Pan-American Exposition at Buffalo, to which very low rates by rail and water will be in effect from Cleveland. Full information as to rates can be obtained by addressing the Secretary, Dr. Henry E. Tuley, No. 111 West Kentucky Street, Louisville, Ky. Members of the profession are cordially invited to attend this meeting. Those desiring to read papers should notify the Secretary at an early date.

Opium in Vermont.—Dr. A. P. Grinnell of Burlington, according to the *Evening Post*, has been making investigations as to the use of narcotics in Vermont, and is astounded at the facts disclosed. His statement seems almost incredible that "in the regular drug-stores and in 160 of the 172 general stores in the State of Vermont there is sold every month 3,300,000 doses of opium besides what is dispensed in patent medicines, and besides what the doctors dispense, which gives one and one-half doses of opium to every man and woman in the State above the age of twenty-one years every day of the year. By a dose one-grain opium, one-eighth gram morphine, one-half ounce paregoric, and twenty drops laudanum is meant. The amount consumed each month means a half dose for every man, woman, and child in the State every day of the year." The facts on which this statement is based were conservatively considered, Dr. Grinnell says. Where information was refused he made no estimates, and the showing of consumption would be even larger if all the sales could be tabulated. No explanation of this undue use of narcotics is offered by the Doctor, but it is ascribed by others in large part to the difficulty of obtaining intoxicants in towns where the prohibition law is enforced.

Bitters and Prohibition.—"Bitters," under which name many intoxicating compounds are sold by druggists in prohibition States, come under the ban of the law in Maine, according to a recent decision by Judge Cornish of Lewiston. The decision is broad enough, too, to shut out many well-known and approved specifics. It was made in a case arising from a seizure in Lewiston of medicine consigned to a physician. The testimony showed that wine was the predominating element in the compound; that it contained 23 per cent. of alcohol; that the wine retained its character as an intoxicating liquor, capable of use as an intoxicating beverage, notwithstanding other ingredients had been mixed therewith. On this showing the Judge endorsed the seizure of the compound. Many proprietary medicines in the market contain a larger proportion of alcohol than the one seized in Lewiston, and if the decision of Judge Cornish is upheld the shipment of any of these medicines into Maine will be in defiance of the law and at the risk of the sender.

Obituary.—Dr. E. Stanley Perkins, a well-known physician of Germantown, Pa., died May 6. Dr. Perkins served in the navy during the Civil War and was for several years demonstrator of anatomy in the Medico-Chirurgical College in Philadelphia.—Dr. Robert Bolling of Philadelphia died May 12, aged 68 years. He was for many years associated with the late Dr. D. Hayes Agnew as demonstrator of anatomy in the latter's private institution. —Dr. Andrew K. Minnick died May 11, of cancer of the throat. He served in the German army during the Franco-Prussion War and was for some time connected with the Jefferson Medical College of Philadelphia.

Dr. Norman Armett Smith died at his residence in Greenwich, Conn., on Sunday night of paralysis, aged seventy-eight years. Dr. Smith was a native of Worcester, Mass.

Dr. James Hayes, one of the oldest physicians in Central New Jersey, died Monday at his home, in Plainfield. The cause of his death was cancer. Dr. Hayes was the son of Dr. Samuel Hayes, who was one of the first physicians to practice in Newark. Dr. James Hayes was the oldest graduate of Princeton University, having received his diploma in 1841. In 1854 he graduated from the College of Physicians and Surgeons in New York, and after a short residence in Brooklyn moved to Plainfield. He leaves a daughter and a son.

Dr. Charles Rice, one of the leading pharmaceutical chemists of the country, and for twen-

ty years chemist of the New York Charities Department, died in Bellevue Hospital May 11th from asthma, at the age of sixty-five years. He had been ill for the past year. Dr. Rice was connected with the Charities Department in various ways for thirty-five years. He was a pharmacist on board a Union war vessel during the war. As a careful student of pharmaceutical science his influence was strong in raising the standards of the pharmaceutical profession. As Chairman of the Revision Committee of the *U. S. Pharmacopœia* he moulded the policy of that standard work. In addition Dr. Rice had an international reputation not only as a chemist, but as a Sanskrit scholar.

CORRESPONDENCE.

THE KARNICE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: "The Karnice" is the name of an apparatus destined to bring help to persons buried alive.

It is the invention of the Russian Count Michel de Karnice Karnichi, who was impelled to his researches by being witness to the narrow escape of a young lady who was thought to be dead and was about to be buried.

The apparatus consists of an iron tube, 10 centimeters in diameter, one end of which is screwed to the circumference of an opening made in the lid of the coffin, while the other end is connected with a small quadrangular metal box containing signals. This box is the only part visible over the grave; the tube is buried in the ground.

Through the whole length of the tube passes a metal rod which enters the coffin below and is connected with the signals above. At the lower end it has a metal ball which is placed 4 or 5 centimeters above the chest of the supposed dead. Whether this ball be pushed or pulled, it causes a sliding movement in the mechanism contained in the box, in consequence of which the box opens, a metal ball is displayed above it and a loud bell is made to ring for a considerable length of time.

The person enclosed in the coffin receives immediately all air necessary for comfortable breathing. A lamp throws light down to him, and the tube serves as a powerful speaking trumpet to make his voice audible at a great distance.

All joints being hermetically closed, no emanation of gases due to decomposition can escape.

When the tube is removed a thick metal plate lined with rubber and moved by a strong spring closes the opening in the coffin.

The box cannot be opened from without. The construction of the apparatus is of the simplest. There is no complicated machinery to get out of order, nor is that unreliable factor, electricity, used at all.

HENRY J. GARRIGUES.
107 East 62d Street, New York.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, May 4th, 1901.

THE FORTHCOMING TUBERCULOSIS CONGRESS—DIFFICULTIES SMOOTHED AWAY—PLENTIFUL INFLOW OF MONEY—FAIR PROMISE OF A SUCCESSFUL MEETING—THE GREAT OFFICERS OF THE CONGRESS: PERSONAL SKETCHES—PROGRAMME OF WORK.

THE affairs of the International Congress on Tuberculosis to be held here in July next, which at one time were in a somewhat critical condition, have lately taken a favorable turn. The Congress will now bask in the light of the royal countenance; the King's patronage has been secured and the proceedings will be formally opened by His Royal Highness the Duke of Connaught, as representing his august brother. The number of adhesions so far is about 700, not including foreign delegates and members who, it is estimated, will make the total up to at least 1,500. This is the more gratifying that it was not unlikely that our Continental neighbours would hold aloof. At the Congress held in Naples in 1900 England was not officially represented at all, and in fact there were only two or three casual Britons present. This was due to the blundering of the Italians who have many admirable qualities but showed little capacity for organization and no idea of businesslike methods or practical management at this occasion. But the absence of the English speaking element—for America was not much better represented than Great Britain—had a bad effect, and led to an attempt being made to ignore us by the formation of a kind of Triple Alliance between Germany, France and Italy for combined warfare against the common scourge. An "International Committee" was formed for the purpose which did not include representatives of any other countries than the three named above. The chief duty of this international committee was to be the organization of Tuberculosis Congresses, but no reference was made to the plan which had been announced some time before of holding a Congress in London. In what relation the forthcoming Congress here is to be regarded as standing to the one held at Naples it would be difficult to say; but it is certain that the "International Committee" has had nothing to do with its organisation.

There appears to be every prospect of a successful meeting. The promoters of the London Congress are naturally highly gratified by the support they are promised from your side of the Atlantic, and Germany has also responded with something like enthusiasm, for the Committee

there formed in furtherance of the objects of the Congress includes the names of the Duke of Ratibor, a very important magnate, who was President of the Tuberculosis Congress held in Berlin, and several of the leading luminaries of medical science in the Fatherland. The great Koch has graciously consented to take part in the show. There was, it is understood, some difficulty in securing him. He expressly stipulated that he should be "on" (as the music hall artistes say) on the first day, and he further insisted on receiving assurances that the second wife whom, as all the world knows, he took unto himself some years ago, should be taken to the bosom of the British matron. An address will also be delivered by Professor Brouardel, the retiring Dean of the Paris Medical Faculty, who is one of the leaders of the campaign against tuberculosis in France. So far nothing has been heard of any star of corresponding magnitude from Italy, but there will doubtless be the usual crowd of delegates of various countries, clad in the swallowtail of ceremony and glittering with orders and decorations.

The financial aspect of the arrangements for the Congress caused a good deal of anxiety to the Organizing Committee at one time, but money is now coming in plenteously notwithstanding the abnormal drain there is on John Bull's purse at present owing to the increasing exactions of the Chancellor of the Exchequer and the large demands of all sorts of charitable organizations for the relief of the manifold miseries caused by the war in South Africa. Already the funds subscribed amount to some 20,000 dollars, and the inflow steadily continues.

The Congress is to be held in the Queen's Hall, close to the Langham Hotel where Americans most did congregate before the appearance of the huge caravanseries which have lately sprung up like fungi in the neighborhood of Charing Cross. The proceedings open on Monday, July 22d, and close on Friday, July 26th. Among the great officers of the Congress those best known to the American medical public are probably Sir William Broadbent, Chairman of the Organizing Council; Professor Clifford Allbutt, Chairman of the General Purposes Committee; Sir James Crichton-Browne, Chairman of the Reception Committee, and Mr. Malcolm Morris, the Honorary Secretary General. Sir William Broadbent is reputed to make the largest professional income among the physicians of this country. It may be well to explain that the term "physician" with us is not used, as I believe it is in America, as a generic name for practitioners of the art of healing; by English use it is restricted to those who limit their sphere of practice to internal medicine. A physician by the very nature of their practice cannot make so much money as a surgeon who has his hands full of work; the former has to sit at the receipt of custom a whole forenoon to earn $150 to $200, while the latter by two or three operations performed before the physician begins his work, may pocket from $1,000 to $1,500. The physician's only chance of earning large fees is by journeys to distant parts of the country, the charge for which is at the rate of two-thirds of a guinea (about $3.50) a mile. Sir William Broadbent spends a considerable portion of his working life in the train, and in this way he makes from fifty to sixty thousand dollars a year. He is a sound physician who, without giving scandal to his brethren by any of those subtle forms of advertising in which many professional Pharisees indulge themselves, has made himself well known to the public. He stands high in favour with royalty, and what is more to the purpose from a financial point of view, he has the power of making himself specially acceptable to rich Hebrews. Yet in one respect Sir William Broadbent is a disappointed man. He nourished the very natural ambition to be the titular and official head of his profession by becoming President of the Royal College of Physicians, but he failed on two occasions to secure the suffrages of the Fellows of the College who choose their President in much the same manner that the College of Cardinals elects a Pope. It is supposed that his failure was due to his connection with the National Association for the Prevention of Consumption, a body which is the motor power of the forthcoming Congress. This Association has from its first beginnings been a stone of stumbling to a sect of the College which thinks that any cooperation with the public in the prevention of disease would necessarily be fatal to its dignity. Though it was obvious that any campaign against tuberculosis, if it was to be successful, must be a people's war, the College would not take the initiative in starting it lest some infection from the *profanum vulgus* should come between the wind and its nobility. Sir William Broadbent in a more philanthropic spirit put himself at the head of the movement, and for this he was punished by the prim academic pundits who have a pretty large voice in the councils of the College.

Dr. Clifford Allbutt is Regius Professor of Physic in the University of Cambridge, and besides being a first rate clinician is a man of wide general culture. His contributions to the great "System of Medicine" which bears his name are marked by a literary grace too rare in medical writers. He is a scholarly physician of the old type now all but extinct, with the fullest equipment of modern science. For character as well as knowledge he stands among the highest in the little group of men who may be taken as truly representative of British medicine. He is one of those personalities whose name of itself places a stamp of respectability on any movement or institution with which it is associated.

Sir James Crichton-Browne was originally what is somewhat ambiguously called in this country a "mad doctor," and he is now a Lord Chancellor's Visitor in Lunacy, an official position which gives him a good deal of importance among those who have to administer our laws relating to the care of the insane. He is an able

man and his co-operation is much valued by the pioneers of movements and the propagators of hygienic ideas on account of his effectiveness as a public speaker. That is a quality much rarer among us than among the citizens of your great Republic, and the gift is proportionately valued. His copious eloquence on any given subject was the secret of Gladstone's power over the mass of his countrymen; and the same in an infinitely lesser degree may be said of Sir James Crichton-Browne.

Mr. Malcolm Morris is well known as a dermatologist and also as the editor of *The Practitioner*, a periodical which was crumbling into decay when five or six years ago he breathed life into the dry bones. To that periodical belongs the credit of the initiation of the campaign against tuberculosis in this country, and its editor has been a leading spirit in the National Association for the Prevention of Consumption, since its foundation. He is to visit America almost immediately after the Congress in order to deliver the Lane Lectures at San Francisco.

The work of the Congress will be distributed among four Sections: (1) State and Municipal; (2) Medical including Climatology and Sanatoria; (3) Pathology including Bacteriology and (4) Veterinary (Tuberculosis in Animals). The first Section is to be presided over by Sir Herbert Maxwell, a Member of Parliament, who though not a physician, is a prominent sanitarian and a charming writer on many subjects. It is to discuss such subjects as the geographical distribution of phthisis in England and Wales; the incidence of phthisis mortality in particular occupations; the statistical evidence against the heredity of phthisis; the statistical study of phthisis in relation to soil; the notification of tuberculosis; the influence of housing and aggregation; the control of milk and meat supplies and the provision of sanatoria. Among those who have promised to take part in the work of this section are Dr. Hermann M. Biggs, of New York; Henri Monod, Directeur de l'Assistance et de l'Hygiene publiques de France, and Dr. A. J. Martin, Inspecteur-Général de la Salubrité de l'Habitation de la Ville de Paris, Membre du Comité consultatif d'hygiène Publique de France; Professor Sheridan Delépine, of Manchester; Dr. Tatham of the General Register Office, Somerset House; Dr. Whitelegge, His Majesty's Chief Inspector of Factories, and a number of medical officers of Health.

The Medical Section of the Congress has for its President Sir Richard Douglass Powell, one of the physicians who ministered to Queen Victoria on her deathbed. He was believed to be opposed to the movement and even delivered a vehement harangue against it some two years ago at the Sanitary Congress held at Southampton. He has since seen the wisdom of moving with the flowing tide. A discussion on Climatology in relation to Phthisis will be opened by Dr. C. Theodore Williams and Dr. Burney Yeo, both of whom are recognised here as authorities on chest complaints. Another discussion will be on "The Therapeutic and Diagnostic Value of Tuberculin in Human Tuberculosis." In this Koch is expected to take part. Professor Clifford Allbutt will open a discussion on Sanatoria for Consumptives. The sections of Pathology and Bacteriology will be presided over by Professor G. Sims Woodhead, of Cambridge, one of the best and at the same time most modest of pathologists. The subjects on the programme are "The Morphological and Physiological Variations of the Bacillus Tuberculosis, and its Relations (*a*) To other 'acid-fast' bacilli, (*b*) To the ray fungus and other streptothrices; The Varieties of Tuberculosis (Morbid Anatomy and Histology); Mixed Infections in Tuberculosis; and the Tissue-changes and constitutional effects produced by the various constituents of Tuberculin." A discussion on this last subject is to be opened by Koch. Dr. Roux and Professor Metchnikoff, of the Pasteur Institute, Paris, are expected to take part in the proceedings.

The Veterinary Section the President of which is Sir George Brown, C.B., one of our leading authorities on the diseases of animals, will debate such questions as "The Diagnosis of Tuberculosis in Animals During Life"; "Tuberculosis and the Milk Supply" and "Legislative and other Measures necessary to combat Tuberculosis amongst Animals." This last discussion will be opened by Professor McEachran, F.R.C.V.S., D.V.S., Chief Veterinary Inspector to the Canadian Government.

In connection with the Congress there is to be a Museum illustrating the pathology, treatment, or prevention of tuberculosis. It will consist of two sections (1) Pathological and bacteriological preparations and specimens illustrating tuberculosis in man and animals. (2) Plans and models of hospitals and sanatoria, charts, and documents bearing upon the historical, geographical, and statistical aspects of the subject.

PATHOLOGY OF DROPSY—SUPRAHEPATIC ABSCESS.

E. H. Starling, at the Pathological Society of London, April 2, 1901, read a paper on the subject of the pathology of dropsy. At the outset he said that he had been able to carry his experiments forward only on healthy normal animals. He had consequently not been able to supply that most exacting test, namely, the observation of the phenomena under the conditions of disease. Dropsy he thought might be defined as an abnormal collection of fluid in the subcutaneous tissues and in the serous cavities of the body due to a disturbance of the balance between fluid-production and fluid-absorption in these same parts of the physiological economy. His experiments and conclusions are based solely on what may be termed *mechanical* dropsy. Many various factors are at work determining dropsy,

which may be classed under two categories; first, such as cause increased transudation, and, second, such as cause decreased absorption of the fluid. Ordinarily the factor of decreased absorption is entirely negligable when compared with the increased transudation and he is led to believe that such is the ruling relation in most cases. The elements at work in lymph-production are chemical and physical. The purely chemical elements may be regarded as diffusion, against which the vessel-walls offer no bar, as there is constantly an interchange through these walls of the fluid without, with that within the capillaries. Whenever increased diffusion occurs it may be postulated that large molecules have for some reason become small and hence more rapidly and completely dialyzable. Under such hypothesis one may account for any local edema as in the inflammatory conditions, but one cannot account for the extensive obstinate or permanent dropsies met with in practice. The physical basis of the increased diffusion rests, first, upon augmented presence of the blood within the capillaries, and, second, upon an increment in the permeability of the vessel-walls. As to this permeability, it is to be borne in mind that in the viscera it is in virtue of their functions greatest, whereas in the extremities it is least. In his experiments, unfortunately, the extremities were the field of observation and always in the presence of this unfavorable factor. Mechanical obstruction to the circulating blood will not produce dropsy whether present in the veins or in the capillaries. It was found necessary to reduce the nutrition of the walls either by the injection of some poison, like tissue fibrinogen, or by the initiation of hydremia. Only after such depreciation of the capillary-wall-nutrition could edema be produced. This was certainly true as regards the dropsy of mechanical pressure by tumor. Cardiac dropsy was slightly different. He had not been able to see why in cardiac disease there should be a rise of blood-pressure, and for the purpose of so demonstrating he employed Cohnheim's device of injecting oil into the pericardium and found that in simple cardiac failure there is a fall of pressure in the capillaries. The factor at work here therefore appeared again to be alterations in the condition of the capillary walls which rendered them more permeable to the blood. An example of this is the fact that in ischemia under conditions of normal blood-pressure there is very marked transudation into the tissues. With regard to the serous cavities, much the same problems were encountered. Simple increase in the blood-pressure would not cause a pleuritic effusion, but so soon as the vessels were damaged or the pleura injured, the effusion promptly took place. In the peritoneal cavity probably the blood-pressure changes were a more potent factor.

W. Ewart spoke of the purely clinical aspects of the question and held that there is a nervous factor at work in these cases of effusion and particularly of localized edema, as found associated with local abscess and gout. Here the vasomotor changes were manifest at once in the redness. In the localized edema of paralyzed limbs there is also probably a nervous factor. Passing now to the more generalized edemas, especially that due to nephritis, his method of treatment by acupuncture and feeding had led him to suppose that here the brain stimulated by the toxicity of the blood took the place of the local nervous influence acting in the circumscribed dropsies. At any rate relief of the edema by drainage and suitable feeding always stimulated diuresis. He thought this could best be explained by the hypothesis he had outlined.

Mr. Daniel, at the Harveian Society of London, March 21, 1901, showed a man who had the following history of a suprahepatic abscess treated by the transpleural method. He had had remittent fever and dysentery with mucoid stools and tenesmus, but without blood, in 1896 when in China as a naval signal man. Since then he had had three attacks of what was called gastritis and the condition was treated as such. At one time a swelling appeared in the right side which was diagnosed as abscess of the liver, but apparently after six weeks of treatment it disappeared. He left the Navy in 1896 and all these attacks had occurred in England between 1897 and 1900. In 1897 he contracted syphilis. The fourth and last attack of the gastro-enteric troubles began in January, 1900, with pain at the base of the right chest, which was not affected by food. The patient was flatulent, anemic and constipated. The liver was not enlarged or palpable and the spleen was in the same condition. He had no definite physical signs but abscess of the liver was suspected. March 16th after a course of treatment for dyspepsia, it was noted that increased pain in the epigastric region had appeared and a month later in April there was deficiency of movement of the right side of the chest and a small amount of pus was suspected. The liver was still not palpable. Three weeks later it was found on admission to fill the epigastric region, part of the right lumbar and almost reached the umbilicus. It was soft, slightly elastic, but presented no definite edge. The patient was much depreciated, pale, sallow, with a temperature of 100.4° F. and great mental depression. The mass showed no fluctuation and was dull all over and caused dulness up to the fourth rib on each side in front and up to within an inch of the angle of the scapula behind. The breath sounds were deficient over the right base. The apex beat was displaced upward and outward considerably. He had epigastric pain and tenderness which were most marked when he lay on his back. He slept well, but perspired freely at times. He also had distinct pain at the tip of the right shoulder, and a slight leucocytosis. Aspiration in the eighth space of the scapular line yielded much chocolate-like reddish-brown fluid which contained tissue-débris and actually disintegrating cells and yielded a pure culture of the

bacillus coli communis. Operation was performed. Free drainage was the outcome and very rapid, full recovery followed. The heart returned to its normal position and every feature pointed to complete cure. Amebæ were found in the walls of the abscess. Eleven months after the operation, the patient feels very much better and says he never felt so well in his life. The right lung has also expanded completely.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, Held at Baltimore, Md., May 7, 8, and 9, 1901.

SECOND DAY—MAY 8TH.

(Concluded from Page 757.)

In response to a most cordial invitation from the Faculty of the Johns Hopkins Medical School the Association convened for this morning's session in its amphitheatre. The Value of bedside Work in the teaching of medicine was the theme chosen by Dr. Osler. In laying special stress upon this, he pointed out that unless a lecturer is specially gifted he becomes not alone a bore but a positive hindrance to the student. Before the moralist can suggest any remedies for existing evils he must have a firm grasp on what is right and what is wrong; ere the medical student can outline a mode of treatment for the sick he must have an equal grasp of the normal, healthy state.

The Cystoscope.—Dr. Kelly next demonstrated his cystoscope catheterizing a patient's ureters as he talked. In connection with some of the difficulties others had had in this work, he said that attention to the little details is absolutely essential to success. The position of the patient; knee chest; the position of the arms and of the face; in fat women, the emptiness of the stomach; the ballooning of the vagina with air; these, and a number of other factors he classified as having special import. In every case of pyurea one should determine the precise source of the pus as early as possible. Occasionally a simple cystitis will not clear up because of a small area of ulceration—this can be seen with the cystoscope, and, if necessary, excised—as he had recently had occasion to do. Too many people who are treated for colitis have a simple proctitis and with the proctoscope this can easily be diagnosed and treated.

Use of the Cystoscope in the Male.—Dr. Young next showed how to reach the male kidneys with as much facility as Dr. Kelley the female. Under purely local anesthesia and in a few moments over three minutes, he painlessly passed double catheters on a patient whom he had never before seen. He made use of Caspar's new and exquisitely finished instrument by which one is able to pass the second catheter without removing the instrument. In the hands of an expert this causes no abrasion of the mucous membrane and consequently blood does not obscure the view.

Relation of Medicine to Pathology.—Dr. Welch then spoke of the relation of medicine to pathology, and gave, in some detail, the essence of the laboratory teaching at the Johns Hopkins. He feels that too much time cannot be spent at the experiment desk for what the student wins in this way becomes a life-long possession. But this laboratory work is in its very essence a study of minutiæ and fundamental general principles must be jealously safeguarded against the inroads of uncorrelated details. To this end he urges that the laboratory work be diligently supplemented by recitation, by lecture and by reading. He felt that the Johns Hopkins was to be very greatly congratulated on the close relationship which existed between the laboratory and the wards. Every student either rents or owns a microscope—his desk for the whole four years is his castle, is his home.

Artificial Fractures.—The section then adjourned to the anatomical demonstration room where Dr. Oscar H. Allis, of Philadelphia, gave a most interesting demonstration of his apparatus for creating fractures and dislocations. This actual observation of the production of the fracture and seeing the broken or dislocated bone subsequently cut out Dr. Allis considers an invaluable aid in the development of surgical sense. By direct downward pressure of the femur upon the fixed pelvis he produced a most beautiful stellate fracture of the acetabulum. This lesion is scarcely recognizable during life. The patient is told he is all right, there is no break only a sprain, and yet disability may exist for months.

Touching their wonderful immunity to fracture which is enjoyed he showed very graphically the extraordinary elasticity of the long bones. In a half dozen consecutive trials the femur sprang fully an inch from its normal line before it fractured. It is known how rare fracture of the neck is in vigorous adults. Dr. Allis demonstrated that direct pressure of half a ton applied between the head of the femur and the condyles failed to fracture at all, increased pressure broke the bone at the shaft's center.

Pancreatitis, with Special Reference to Chronic Pancreatitis.—Mr. A. W. Mayo-Robson of Leeds, England, in a few graceful words thanked the Association for the honor it had heaped upon him. Plunging deep into his topic, at once, he expressed both surprise and pleasure that so much had recently been written on pancreatitis and pancreatic surgery. But, much as may of late have been gained, there is still a very great shroud enveloping the disease and even with our most recent applications of pathological and physio-

logical chemistry, and in the light of a free and open incision, we are often sadly in the dark as to diagnosis. Ten years ago marked the birth of this last child of surgery. Up to that time the chronic form of pancreatitis was always confounded with cholecystic inflammations, while the acute invariably passed unchallenged in the dark depths of the abdomen. Inflammatory changes which have long been recognized in the bile ducts have their counterpart in every detail in the pancreatic ducts—sometimes jaundice is present, at other times not. It seems strange that while choledochotomy has been done these ten years, we are only just beginning to appreciate that what obstructs the common bile duct also often blocks the outlet of the pancreas.

Etiology of Pancreatitis.—In speaking further of this feature he drew attention to the minute anatomy of the gland. Unlike the parotid it has but little supporting tissue, hence although deeply placed, the slightest trauma may give serious sequelæ—indeed, the gland is probably very often injured in gall-stone operations. Simple and infective pancreatitis exists, just as in the liver corresponding forms of hepatitis are found.

Symptoms of Pancreatitis.—These are as yet but vaguely distinguished from affections of the gall bladder; indeed, when complicated with jaundice one cannot differentiate these conditions. It is, however, generally agreed that an extensive and rapid loss of weight is very significant, particularly in the presence of clay-colored stools. Glycosuria is a tolerably constant symptom, but it appears too late to be of any diagnostic value. Fat necrosis is to be expected, although it is found only after operation; and, since it occurs in other conditions, is not pathognomonic. Lipuria has been cited as an aid in diagnosis, but recent researches show that but little of the accumulating fat passes by means of the urine. As a rule, then, germ infection through the duct, or by contiguity, is the most probable etiological factor, while a sudden loss of weight, with or without jaundice and accompanied by white stools is the most constant symptom. That the pathology of fat necrosis has a very important bearing on the treatment, particularly of the hemorrhagic form will be seen by the history of its degeneration. The fat splits into a glycerine and fatty acid, these unite with the calcium salts of the blood, thus reducing its power of coagulation. Calcium in some form is indicated in heroic doses. The glycerine one would expect to develop an aldehyde, but this is not the case. If the urine in a case of pancreatitis be tested with phenyl-hydrazine singularly arranged yellow crystals appear very constantly. Mr. Mayo-Robson does not yet know their composition, but he suggests that they may be a by-product of the glycerine and finds them of great use in making a differential diagnosis between ordinary inflammatory jaundice and icterus complicating pancreatitis. One very interesting question in connection with this fat necrosis is, if it be the direct result of a blocking of the duct, and absence of the secretion, why is fat deposited in regions so distant from the pancreas, as for example in the myo—and pericardia? Hemorrhage, probably the direct result of the reduction of the calcium of the blood, may supervene at any moment, and cause death very suddenly. It often coexists with cancer. May occur far distant from the seat of operation and gives no prognostic signs of its advent.

Treatment.—The drug treatment consists in the administration of chloride of calcium gr. xxx. three times daily for two days prior to operation and the same amount by enema for two days after. If hemorrhage should begin after operating, it can be controlled and the patient saved by heroic doses of this drug.

Hemorrhagic Pancreatitis.—Much has been said and written about this condition. It is a term suitable only for certain conditions, some of which are as follows: (1) In cerebral disease there is a general tendency to pancreatic hemorrhage; (2) bleeding may occur with, or without jaundice; (3) acute and chronic forms of pancreatitis may occur without hemorrhage. Accordingly we would classify pancreatitis as the acute, subacute and chronic—the hemorrhagic form being only a type of the acute. The treatment of the acute form calls for immediate operation just as urgently as acute appendicitis. Mr. Mayo-Robson usually operates through an anterior incision for this and for the subacute form with a counter incision for drainage through the left costo-vertebral angle. Chronic interstitial pancreatitis often simulates malignant disease, and explains those cases of extraordinary recovery where carcinoma had been diagnosed, ninety per cent. of the chronic cases recover after drainage is indirectly established via the gall bladder.

Dr. George E. Brewer of New York in discussion said that he would deal not so much with the clinical side of pancreatitis but with the surgical anatomy and embryology of the organ. Early in the fifth week of fetal life two buds develop from the middle region of the alimentary canal. One projects upward to become the liver, the other downward to develop into the pancreas. By a process of division and subdivision this bud which projects back into the posterior mesentery gives rise to the two pancreatic ducts, the lower series of buds yielding the canal of Wirsing; the upper, that of Santorini. It has always been held that this latter is closed in 90 per cent. of all cases, but he has found, rather, that it is *open* in 90 per cent. of all cases. From an etiological standpoint this discovery is of paramount importance for it shows the continuous path which exists from pancreas to gall-bladder when the lower common duct is blocked. There are three

chief variations in the duodeno-cystic opening: (1) They may be double; (2) duct of Santorini may open into the common bile duct; (3) there may be three separate openings. Dr. Brewer then turned his attention to the second special point in his discussion—the direction in which pus from the pancreas most frequently gravitates. Embryology again points out this path and demonstrates why it is so invariable. The history begins with the rotation of the stomach, which forms the lesser peritoneum, and casts three layers of fibrous tissue to the rear abdominal wall. These, being functionless, fuse and ultimately merge into areolar tissue. Thus the pancreas becomes a retro-peritoneal organ and its areolo-adipose tissue becomes directly continuous with the fatty capsule of the left kidney. Among the minor points considered, Dr. Brewer asked whether the hemorrhage of the acute form of pancreatitis may not arise from a sort of auto-digestive action of the pent-up secretions. A final point in the anatomy of this region consisted in a reminder that the papillary opening of the conjoined ducts has in many cases been found to be abnormally large. Paralysis of the sphincter favors ascending infection by bacillus coli communis and he feels that certain forms of pancreatitis may be explained in the same manner as ascending pyelonephritis. In closing he urged the great necessity of loin counter incision for drainage.

Dr. E. L. Opie of Baltimore said that the common bile duct receives the pancreatic duct just prior to its entry into the duodenum. For a short and variable distance the two run in company and separated only by a diaphanous membrane. The cloaco-duodenal orifice is much narrower than the opening of either duct consequently it is the most common lodging point for stones. It can readily be seen that there will be all the difference in the world in the effects of a large and a small stone. The large one closes all three openings, the small stone passing well beyond the opening of the ducts closes only the cloaco-duodenal opening. This last condition was found in a Johns Hopkins case; there was a direct, unobstructed path from liver to pancreas. That bile may be a very important factor etiologically is substantiated by the fact that subacute pancreatitis and death followed the injection of bile into the pancreatic duct in five dogs, consecutively.

Dr. J. W. Elliot of Boston thinks that jaundice is a very common symptom of pancreatitis and believes that gall-stones are its most frequent cause. He cited several cases in which cystic drainage effected cures.

Dr. Geo. R. Fowler of New York cited three important cases. The first had fearful pain; on operation, fat necrosis was marked; there was much thin dark fluid about the pancreas; drainage; death; autopsy confirmed the diagnosis. The second presented to a very marked and alarming degree three distinct attacks of extreme depression. They simulated the profoundest shock. After recovery from the third attack and under strychnine the patient rallied enough for operation. Recovery ensued after prolonged drainage. In the third case only was jaundice present, it had existed for over two years—this man had the characteristic collapses but recovered after drainage.

Dr. H. L. Carson of St. Louis cited a case of chronic pancreatitis in a young woman where the symptoms were so disguised that it was only after two years and several operations that she finally recovered after marsupialization of the gall-bladder.

Dr. W. L. Estes of Easton, Pa., recalled a case which had been operated upon for cholelithiasis. The head of the pancreas had been found to be so enormously enlarged that it was diagnosed as carcinomatous. Nevertheless the patient continues well. Another case was of traumatic origin, followed a slight blow on the abdomen. In this instance the only sign was a tremendous loss in weight from 160 lbs. to 95 lbs. After five weeks a great tumor developed which contained 2,500 c.c. of pancreatic fluid and which discharged copiously during recovery.

Mr. Mayo-Robson in closing said that gall-stones are the great causative factor of chronic pancreatitis although they may have been passed long prior to the operation. Dr. Fowler's series of collapses was of peculiar interest: did he feel that they rallied because of the strychnine? From Dr. Opie's discussion he had learned the very important rôle which may be played by the bile, but is this bile ever sterile? Dr. Brewer's demonstration of the frequent patency of Santorini's duct explains those obscure cases where a stone has blocked the lower common bile duct.

Treatment of Chronic Ulcer of the Stomach.—A. W. Mayo-Robson said that the technic and the daring originality of the modern surgeon has made ulcer in a measure a surgical disease. Of the 25 per cent. which fail to respond to medical treatment in from four to five weeks almost every one should undergo operation. It is from these cases that we reap the appalling death rate which it is safe to put above 30 per cent. There are now quite enough statistics to show that by operation this rate can be reduced to 5 per cent. After enumerating the well known operations for the relief of ulcer Mr. Mayo-Robson said that prolonged preparations directed toward the sterilization of the gastric mucous membrane were quite unnecessary. It is predisposed to be aseptic, aseptic foodstuffs and occasional lavage two days prior to operation suffice. Gastro-enterostomy will doubtless be the operation of choice for many years, because of its low mortality. It secures drainage and rest, it relieves hypochlorhydria, it is curative. He prefers the posterior operation which can easily be done in a quarter of an hour by the use of his bone bobbins. Pyloroplasty, in the absence of adhesions and in the presence of a properly placed ulcer deserves great considera-

tion. In conclusion Mr. Mayo-Robson demonstrated on cleverly prepared models the use of the bone bobbin and certainly, in his hands they seem well-nigh ideal.

Dr. J. W. Mayo, of Rochester, Minn., spoke entirely on gastro-enterostomy. He prefers the anterior operation, stating that in 63 cases he had had but 1 per cent. of mortality.

Dr. T. A. McGraw of Detroit said that the only possible objection to his method of making anastomosis by means of an elastic ligature, is that it takes from 60 to 70 hours for the ligature to cut through. In gastro-enterostomy this delay is of no consequence. It is the cleanest, safest and quickest method.

Dr. W. G. McDonald of Albany reported two cases in which he thought a more radical operation than gastro-enterostomy would have prevented the development of carcinomata which, within two years proved fatal. The ideal operation is extirpation.

Dr. W. L. Rodman of Philadelphia felt that excision is always indicated in those ulcers which are located anteriorily. Unfortunately they are in the minority.

Mr. Mayo-Robson in closing the discussion thanked the Association for the many courtesies which had culminated in his presenting these papers in America.

Pulmonary Insufflation for the Prevention of Surgical Pneumothorax with Demonstration of New Apparatus for Artificial Respiration.—Dr. R. Matas of New Orleans directed attention to the great importance of intralaryngeal insufflation in place of any variety of face mask. In these there is great danger of filling the stomach rather than the lungs. In discussing the Fel-O'Dwyer apparatus, he pointed out that it failed in two important details; it lacks a manometer, which shall automatically regulate the pressure employed, and a self-acting cut-off to govern the amount of air used.

Third Day—May 9th.

Resection of the Chest Wall for a Large Sarcoma; Successful Use of the Antistreptococcic Serum.—Dr. W. W. Keen of Philadelphia gave the details of this operation in full and in conclusion laid stress on the following points: (1) the method of separating the tumor from the chest wall; (2) the anterior and posterior division of the ribs prior to opening the plural cavity diminishes the danger of collapse of the lung; (3) Fel's apparatus with mouth-piece is unsatisfactory—he prefers the Matas-Bloom device; (4) the suture of the lung to the chest wall was followed by no untoward result and it distinctly diminished postoperative shock; (5) blood examination was of the very greatest value in that it demonstrated a free streptococcus septicemia, and yielded a very clear indication for the administration of antistreptococcic serum.

Venous Aneurism of the Right Subclavian Artery and Vein.—R. Matas of New Orleans spoke of the history of this operation; of some of the grave difficulties attending it and of the more important details of his technic. In all but 15 cases are recorded, but only 4 of these fall in the domain of modern surgery. In all probability it is better not to operate on traumatic aneurisms of the subclavian. The gravest difficulty arises from hemorrhage which Rivington's loop in this case entirely failed to control. The more important technical points were first the use of massive infiltration anesthesia which enabled two hours' work to be done without the need of chloroform, and second, successful lateral phleborrhaphy of the anastomotic outlet.

Dr. A. D. Bevan of Chicago discussed the following questions: (1) Proximal and distal ligation of the artery without tying the vein; (2) hemorrhage from the vertebræ is usual; (3) prognosis in unoperated cases is surprisingly good; (4) gelatine injections may help.

Dr. T. A. McGraw stated that the type of aneurism was the deciding factor as regards amputation. The traumatic aneurisms are stationary; the atheromatous progressive.

The Following Papers Were Read by Title.—Subtrochanteric Osteotomy by Dr. E. H. Bradford of Boston; Operative Indications in Tumors of the Liver with a Report of Cases by W. G. MacDonald of Albany; Congenital Sacrococcygeal Tumor of Large Size by Chas. A. Powers of Denver; Vicious Circle after Gastro-Enterostomy by T. A. McGraw of Detroit; A Case of Splenectomy for Myelogenous Leukemia by M. H. Richardson of Boston; Congenital Anterior Dislocation of the Tibia Treated by Arthrotomy by J. B. Roberts of Philadelphia.

Phlebitis Following Abdominal Operations.—Dr. A. Vander Veer of Albany in speaking of the etiology of this condition expressed surprise that in view of the trauma to which the abdominal veins are exposed during operation it is so uncommon. With no hand to guide or limit its advent or its progress it is always unexpected. None can say of these dread changes whether they are pandemics like grippe, or atmospheric conditions, or gaseous influences. Whether the omnipresent germ or too tight post operative abdominal bandaging have any bearing, it is impossible to say. Immediately after moving into the new Albany Hospital he had four cases in every one of which the primary wound healed by first intention. Since the disease is more frequently seen on the left side the possibility suggests itself that, as in varicocele, the distribution of the left abdominal veins may be a factor worthy of consideration.

Dr. Geo. R. Fowler said that the importance of this lesion varies with the frequency of its occurrence, with its mortality rate, with the duration of resulting disability. In a study of 3,000 of his more recent cases he found that .59 per cent. developed phlebitis. Two were double; ten followed septic appendectomies. He considers

the more important clinical signs to be as follows: (1) onset never before 10 days to 3 weeks after operation; (2) dull pain over the femoral vein and above Poupart's ligament; (3) rarely begins with a chill; (4) there is often an increased pulse rate with no corresponding rise of temperature; (5) one can palpate the rope-like veins; (6) edema is not marked if the patient stays in bed; it develops on standing. The prognosis for life is good; disability usually exists for from three months to a year. The treatment is as near absolute rest as is possible and counter-irritation. He uncompromisingly condemns the excision of the vein in which ultimately, without exception, the function is completely restored.

Dr. W. J. Mayo cited twelve cases. Three of these had a complication from which the cases of the previous speaker had been free—pulmonary embolism. One died chiefly because of his too strong heart; the pulse of the others became almost imperceptible—this factor no doubt saved their lives. In one-half of his cases the lesion was on the right side.

Operation For the Radical Cure of Umbilical Hernia.—Dr. W. J. Mayo of Rochester in detailing this operation which he has successfully used in 19 cases, said that it seemed particularly indicated in cases where the recti had degenerated to mere fibrous ribbons. He overlaps the fasciæ and frequently closes the wound at right angles to the mid-line. It gives a sense of firmness equaled by no other technic.

Dr. De Forest Willard of Philadelphia cited a case where the patient weighed 300 lbs.; he had successfully operated through eight inches of fat.

Umbilical Hernia.—Dr. J. C. Warren of Boston, in reference to the etiology of umbilical hernia spoke of the diffuse lipomatous fold almost always present in these persons which, in the upright position tugs incessantly at the umbilical cicatrix. He suggested the removal of this layer as a post operative prophylaxis.

Dr. Mayo, in closing, said that he always removed as much omentum as continuously extruded from the wound.

Prevention and Cure of Post Operative Hernia.—Dr. James E. Moore of Minneapolis said that with the modern technic and care in closing abdominal wounds the occurrence of a hernia following operation was something of a disgrace to the surgeon. He said that practically no one in the Northwest now uses any other than absorbable suture material. As to the indications for operation, he feels that it is much easier to give the contra-indications which can now be counted on the fingers of a single hand.

Dr. A. D. Bevan of Chicago cordially endorsed all that had been said in favor of absorbable sutures and favored formaldehyde catgut, which is both strong and sterile. In regard to the position of incisions for abdominal work he felt there was too much disregard to the injury of nerves and blood vessels. As determined by the position of these, there exist certain very well defined normal incision lines—the abnormal lines should be used as little as possible. He mentioned a so-called auto-suture which was being used in Chicago in Bassini's operation. It is a narrow ribbon of tissue frayed from the aponeurosis of the transversalis by which the latter is sewed to Poupart's ligament.

Officers Elected.—At the executive session the following officers were chosen: President, De Forest Willard of Philadelphia; first vice-president, Robert Abbe of New York; second vice-president, R. Matas of New Orleans; treasurer, Geo. R. Fowler of Brooklyn; secretary, Dudley P. Allen of Cleveland; recorder, Richard H. Harte of Philadelphia. The next meeting will be held at Albany, N. Y., about May 20, 1902.

Fractures and Dislocations of the Spine.—Dr. S. H. Weeks of Portland said that dislocation without fracture is unknown except in the lower cervical region. It is usually caused by hyperflexion, the upper part of the spine being almost invariably displaced forward. The so-called facture-dislocations are found in all other parts of the spine. The treatment is in every case immediate and liberal laminectomy, to which there are practically no contra-indications in a pronounced case. Whether the dura should be opened or not is a problem not yet solved, though he feels there are very few contra-indications to opening it.

Dr. John C. Munro of Boston said that the outlook is always bad in these cases. It is the surgeon, not the neurologist, who should decide as to operation. He feels that the dura should always be opened and left open to avoid any possible pressure on the cord.

Dr. S. J. Mixter of Boston favors immediate operation even in the cervical region; he does not suture the dura.

Radical Cure of Inguinal and Femoral Hernia with a Report of 800 Cases.—Dr. W. B. Coley of New York spoke first of inguinal hernia in the male. He emphasized the desirability of absorbable sutures and in addition to other technical points stated that the use of rubber gloves had reduced his percentage of infections from four to less than one-half of one per cent. He has had excellent results in 150 cases of inguinal hernia in the female.

Dr. J. C. Warren of Boston feels that there is too great a tendency to operate on children. It must not be forgotten that trusses frequently cure these patients, even as late as the twenty-first year. He prefers silk to any other form of suture, feeling that it is so bland when buried in the tissues as virtually to be absorbable.

Dr. W. T. Halsted of Baltimore said that for the past two years he had discontinued transplanting the cord. The two most important points in his technic at present consist in the removal from the cord of all superfluous veins and in the use of buried silver wire. More than 500 herniotomies have been closed with silver wire; 25 have suppurated but the sutures had to be removed in two cases only. In 227 appendectomies

over 1,000 buried sutures have been used, of these only four had to be taken out.

Dr. Coley, in closing, said that he does not usually advise operation after 60. Silk is the least irritating of all non-absorbable sutures.

Pneumonotomy, with Exhibition of the Patient.—Dr. W. J. Hearn of Philadelphia exhibited a case of abscess of the lung which he had successfully drained in the axillary line. He is at a loss to know how to close the sinus since it communicates with a bronchus.

Silver Wire and Electricity in the Treatment of Aneurisms.—Dr. L. Freeman of Denver has had two cases, one of which is apparently cured, while in the other the aneurismal wall has at least doubled in thickness. Not feeling content that Hunter's experiments with the coiling of silver wire in glass bulbs really typified the conditions as they exist within an aneurism, and believing that soft silver wire is better than the drawn variety recommended by Hunter, he hollowed out a large turnip and experimented wiring this artificial aneurism. He concludes that the soft wire gives by all odds the better results, and feels that the best results can be obtained only by the use of over 200 feet in large thoracic tumors.

Dr. J. M. T. Finney, of Baltimore, cited eight cases which he had wired. In two there was apparent cure; in two death was hastened; in two the pain was temporarily relieved; in two the operation was too recent to report. The results may not be immediate. In general he does not look upon the operation with favor.

Dr. De Forest Willard cited a case in which much had been gained by the employment of this method. He employs a very moderate current: 10 20 mille-amperes.

Dr. R. Matas has studied the matter from the standpoint of abdominal aneurisms only. Some of his limitations and conclusions were as follows: (1.) the aneurism should be sacculated; (2.) it should be unilocular and its walls thin; (3.) atheroma contraindicates wiring; (4.) the lumen should be small. These facts, unfortunately, cannot be ascertained during life.

Movable Kidney; Its Cause and Treatment.—Dr. M. L. Harris of Chicago presented an admirable series of tabulated measurements of men, women and children by which he attempted to show that the kidney's position bears a certain definite relation to the body form. He divides the abdomen into three zones, the middle one of which lodges the kidneys. In cases of evident movable kidney the cubical contents of this zone is found to be very much below the normal. This suggests a new and more rational form of treatment, which consists in limiting the area of the lower zone rather than forcing the organ up into an area from which it has been expelled for lack of room.

Nephrolithotomy on Both Kidneys.—Dr. S. J. Mixter of Boston showed skiagraphs of a case in which unusually large deposits had been found. He considered it very unusual that no degenerative changes had been induced by their presence; and that there had not been found the slightest trace of pus or blood in the urine.

New Method of Closing Defect Following Thorough Removal of Breast.—Dr. S. J. Mixter of Boston considers that the smaller the malignant mass the more extensive should be the operation. Feeling that one of the great factors which cause women to particularly dread the removal of a breast lies in the extensive disfigurement he now, by a series of liberating incisions slides the healthy breast over to the middle line, thus closing the entire wound by a single line of union.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 21, 1901.

The President, Robert F. Weir, M.D., in the Chair.

THE scientific business of the session consisted of a discussion on the modern treatment of gonorrhea and its complications and sequelæ. The following papers were read;

"Acute Gonorrhea," by G. K. Swinburne, M.D., "Chronic Gonorrhea," by John Van der Poel, M.D., "The Complications of the Posterior Urethra," by J. Pedersen, M.D., "Gonorrheal Conjunctivitis," by W. A. Holden, M.D., "Gonorrheal Stricture of the Urethra," by J. R. Hayden, M.D.

All of these papers, by special arrangement, appear in this week's issue of the MEDICAL NEWS.

Treatment of Acute Gonorrhea.—Dr. Robert W. Taylor said that on an occasion like this, when there is a battle royal over methods old and new, a veteran rejoices to be on the fighting line. The treatment of acute gonorrhea constitutes the most important chapter in genito-urinary surgery. There is, unfortunately, in modern times an easily-noticeable tendency to extreme measures in the treatment of gonorrhea. This is not reflected as much as one might expect in the papers read to-night. The general tendency seems to be toward a conservative eclecticism, though, of course, as might have been anticipated from younger men, there is a good deal of talk of the usefulness of the new silver salts.

Some Old Ideas.—With regard to the treatment of gonorrhea he said he has some very emphatic ideas. Years ago the armamentarium of the physician for the treatment of "clap" consisted of the use of antiblenorrhagic internal remedies and the injection of an astringent solution. We have advanced beyond that and perhaps should forget a good many of the things that were recommended rather confidently at that time, but we must not forget too much. It is the custom for the

physician of the present day to turn up his nose at the old-fashioned "clap" injection and the use of antiblenorrhagic internally. There is no doubt in his mind, however, that in four or five years most of the medical profession will go back to these remedies in a conservatively eclectic way.

Abortive Treatment of Gonorrhea.—Dr. Taylor has never been very much impressed with the abortive treatments for gonorrhea so often highly recommended. In a large practice, extending over many years, he has perhaps seen eleven cases, not more, in which he thought that an acute gonorrhea had been aborted by treatment. For some time we have been passing through what may be called the permanganate stage of the treatment of gonorrhea. Just as many ardent advocates as the permanganate treatment has now, the bichloride treatment had fifteen or twenty years ago. It is scarcely necessary to say that the bichloride treatment is no longer in active use.

Irrigation Treatment.—Contrary to the opinion of many genito-urinary surgeons, he is inclined to think that most of the flushing out of the urethra, especially during the acute stage of gonorrhea, is injurious. The passage of a stream of water under pressure (and the occurrence of some pressure is absolutely unavoidable) is always a source of irritation. The bulging out of the urethra under the pressure of the injected fluid causes injury of the delicate cells of the urethra, separates them from one another, irritates them and gives rise to a certain amount of inflammatory reaction.

Selected Treatment.—For the treatment of an ordinary attack of acute gonorrhea, all sources of irritation should be avoided as much as possible. The penis should be soaked freely and often in hot water, should be washed frequently in boric acid and boric acid and the alkalies should be used internally. The patient should be put at rest and the bowels should be kept loose. After the third day, the penis should be wrapped in warm lead-water and laudanum, in order to relieve pain and burning. A little later in the course of the disease, weak permanganate injections should be given, but not in large quantities, nor too frequently. With the subsidence of the discharge, antiblenorrhagics will be found to do good. They will usually be indicated from the tenth to the fourteenth day, when the alkalies should be stopped. The internal medication must be kept up for some time.

Silver Salts.—The reason why we hear so much about the new silver salts is that the younger men do not realize how to use nitrate of silver properly. They have used it in too strong solutions and have naturally obtained an inflammatory reaction. There is no doubt that the silver salts are very effective bactericides for the gonococcus. Hence the popularity of the new silver salts which do not irritate. We may obtain the good effects of the nitrate of silver without any bad results by using a solution of 1-32,000 or up to 1-20,000. One to two ounces of such a solution should be used at a time. If the discharge becomes slightly more copious and then lessens in amount, but without inflammatory reaction, the strength of the solution of silver nitrate may be increased to 1-10,000 and even to 1-5,000. At the end of six to seven weeks instillations of nitrate of silver in the strength of 1-500 may be given. This will be the ideal treatment of gonorrhea in the future.

Various Astringents.—We hear a good deal said of the longevity of the gonococcus in our day, but we must remember that long ago Ricord said it is easy to know when a gonorrhea begins, but very hard to tell when it will end. Meantime we must not forget that some of the astringent solutions suggested by Ricord, as, for instance, the chloride of zinc solution may still prove of good service, especially toward the end of a case of gonorrhea when the discharge is but slight and other symptoms have practically ceased. A solution of sugar of lead may also prove of service. Not every case of gonorrhea will yield to the same astringent even toward the end of its course. It may be necessary to try several in succession. Under these circumstances a dilute solution of sulphate of copper will sometimes be found useful.

Pathological Basis of Gonorrhea.—Dr. Lapowski said that when we consider the underlying reason of the discharge in gonorrhea we can understand much better the reason why the disease often proves obstinate to treatment. Within twenty-four hours after the discharge is first established the gonococci have found their way into the glands of the urethra. When solutions of protargol are first injected they fail to reach the gonococci concealed in these glands. There are cases of gonorrhea in which the gonococci remain on the surface of the mucous membrane. These can be cured immediately. These cases help to furnish the examples in which the abortive treatment of gonorrhea has been successful. Gonorrhea of the conjunctiva can be completely eradicated. There, of course, we can secure absolute physical and physiological rest for the inflamed mucous membrane. Urination and erection, with the consequent hyperemia, make it impossible to obtain absolute rest for the urethral mucous membrane and so inflammations of it become inveterate. Dr. Lapowski has seen a case in which injections of protargol had been used faithfully for four months, yet gonococci were demonstrable in the secretion.

Complications of Gonorrhea.—The gonococcus is now known to invade nearly every large organ. It has been found on every serous membrane on the body—in the arthritic cavities, in the endocardium and pericardium, in the peritoneum, and on the meninges. It has been known to produce endosynovitis and

other seromembranous inflammations. The gonococci have been demonstrated in the blood some seven times and have been found on lesions of the heart valves and serous linings in a very large number of cases. It has been found in the spleen and in pure culture in intramuscular abscess and has been known to produce erythema nodosum of the skin.

Gonorrhea and Marriage.—There are some authorities who say that the existence of a purulent discharge in which gonococci can not be demonstrated does not contra-indicate marriage. Other authorities are not of this opinion. The microscopic diagnosis of gonorrhea is not final. There are certain involution forms of the gonococcus which do not take Gram's stain. Wasserman has shown in a recent case that these involution forms occurred on the endocardium and pericardium when ordinary forms of gonococcus were found elsewhere in the system. Only one thing remains to be said with regard to gonorrhea. Prophylaxis is the best method of preventing the ravages which the disease produces upon the human race, and the limitation of reproduction which it brings about. There is no method of treatment that can be trusted with any degree of confidence and in general we know too little about the types of the disease and the reasons for its chronicity for us to say anything very definite about its treatment as yet.

Gonorrheal Auto-Infection.—Dr. Ramon Guiteras said that occasionally fresh discharge is set up in patients who have not been exposed to infection and whose wives are above suspicion. It is evident in these cases that the cause of the disease is a self-infection from old lesions existing in the posterior urethra. These conditions are often spoken of as "strains." They are really rekindling of old foci of disease and the spread of the infectious agents over previously healthy parts. In many of these cases, Dr. Guiteras has found a seminal vesiculitis and this was evidently the source of the new infection.

Gonorrheal Treatment.—The question of treating gonorrhea is, of course, a very difficult one and may be approached from many sides. Dr. Guiteras has seen numbers of patients cured by copaiba and sandal wood when they did not care to take injections. In some cases patients have gone to homeopathic physicians and taken little pellets and yet been cured. There is no doubt that the astringent remedies, zinc, and lead and alum, will continue to be used. Of the newer silver remedies, argol, argonin and protargol, the last seems to be the best. Protargol has given better satisfaction than mercurol. Solutions of silver salt seem to have a specific bactericidal effect for the gonococcus.

Irrigation Treatment.—Irrigations of permanganate of potash have certainly been of very great service in the treatment of gonorrhea. The special precautions to be taken are that the hydrostatic pressure must not be high, and no shock must be given to the compressor muscle. The effort to pass the muscle should be made two or three times at intervals, rather than continuously for any length of time. There seems no doubt that fewer strictures have occurred since the use of permanganate irrigation has become more general. Since the introduction of this method of treatment, however, more seminal vesiculitis has been noticed. This is perhaps due to the fact that our methods of diagnosis have improved and cases of seminal vesiculitis now seldom fail of recognition.

Individual Not Routine Treatment.—Dr. Charles H. Chetwood said that there is too much routine in the treatment of gonorrhea. There are two general methods—the antiphlogistic treatment, which institutes mild measures at the beginning until the acute stage of the disease has passed; and the other, which wages direct war upon the gonorrhea and which may be called the antiseptic method. This latter curtails the length of the disease and lessens complications. It is not its purpose to destroy all the gonococci at one application. The gonococci lying on the surface of the tissues are destroyed and the urethra is made more uninhabitable for the microbes. Irrigations are not for the acute stage of the disease, as they add to the inflammatory reaction by irritation. At first only the anterior urethra should be treated. After five or six days, irrigation of the whole of the urethra should be employed, on the principle that to stop the spread of a fire water should be thrown on a house which is close to the fire. By the antiseptic method of treatment, symptoms are rendered much less annoying. There is less ardor urinæ and chordee and the same lessening of symptoms is noted with regard to the posterior urethra.

Gonorrheal Prophylaxis.—Dr. F. Bierhoff said that no mention had been made of a prophylactic treatment of gonorrhea. This is of two kinds, general and personal. The first requires supervision of the sources of infection, that is, control of the prostitute. Much good can undoubtedly be accomplished in this way, though, of course, the evil cannot be entirely eradicated. The regulation of prostitution should not be in the hands of the police, but of the sanitary authorities. This transfer of authority in these matters would surely result in better enforcement of the regulations. Dr. Frank of Berlin proved that it was possible to prevent the development of gonorrhea by the injection of a few drops of a twenty-per-cent. solution of protargol. Virulent gonorrheic material was injected into the urethræ of six males. Three were left untreated and three were given preventive treatment. In none of the latter three did gonorrhea develop. In the others on the first sign of discharge the abortive treatment with protargol was employed

and the disease was quickly cured. At Stockholm the experience has been that with a four-per-cent. solution of protargol the disease can be prevented if the solution is employed within ten hours after suspicious intercourse.

Picric Acid in Gonorrhea.— Dr. Hill said that picric acid, as suggested by Guyon in 1899, was a very efficient remedy in a certain stage of gonorrhea. After the frankly purulent discharge has ceased and a mucoid discharge supervened with threadlike fibers in the urine, picric acid is the most effective agent for the cure of the persistent low grade inflammatory condition that remains. The picric acid is used in a solution of 1-100 or 1-200 and about twenty to sixty minims should be introduced at one time.

What Is Gonorrhea?—Dr. F.C. Valentine of New York said that the trouble with the treatment of gonorrhea is that we do not know what gonorrhea is. Urethral discharges are not all of them identical in type even when caused by the gonococcus. There are several forms of gonococci and what we need more than special germicides is the knowledge of methods for the differentiation of the various forms of gonorrhea and the special treatment needed for each form. All cases cannot be treated in the same way; they must be treated individually. There is one thing that is needed in the treatment of all cases and that is exceeding gentleness. Any treatment that causes irritation and pain does more harm than good. Surgeon Woodruff announces that he has had good results in the army, in the treatment of acute gonorrhea, by the irrigation of the urethra for hours continuously with decinormal salt solution. This form of treatment, of course, can only be employed in the army. The use of cocaine has been suggested in order to make the urethra anesthetic for instrumentation and manipulation. Its use has been suggested as a preliminary to irrigation. Any one who has had much experience knows that the result of using cocaine is to cause more pain for a longer time afterward, and what the patient may lose in intensity of pain at the moment the instrumentation is employed is more than made up for by the length of time during which he must suffer afterward. The only anesthetic that a genito-urinary surgeon can employ successfully is that of exceeding gentleness. Experience and practice will soon teach that it is an adequate one.

BOOK REVIEWS.

The Feeding of Infants, Home Guide for Modifying Milk. By Joseph E. Winters, M.D., Professor of the Diseases of Children, Cornell Medical College. E. P. Dutton & Company, New York.

This little book is a record of personal experience and the well-known success of the author as a practitioner renders such a record one of value. It is designed as a guide for the home modification of milk. The method of formula is adopted, ten being devoted to the changes required during the first year. Each formula is accompanied by a percentage statement, for it is clear that the author thinks in percentages and takes each step with a very definite idea of what he wishes to accomplish. The one source of uncertainty is that encountered by every similar method of home modification—the errors which must result from the every-varying composition of different samples of milk. Every observer, however, must agree with the author's statement that children can get over slight chemical differences in cow's milk much more readily than they do physical differences—those due to contamination.

In studying the formulæ, one is struck by the fact that the percentages vary decidedly from those used by most writers. The fat and sugar are unusually high; the proteid low, particularly during the first months. Two per cent. of fat is given on the first day and four per cent. in the fourth week, a percentage reached by most authors by the end of the third month. Seven per cent. of sugar is given on the first day. Of proteids, one-fourth of one per cent. is given at the outset, one per cent. being reached in the fourth week and two per cent. in the fifth month.

The low percentage of proteids used during the early weeks is no doubt due in part to the unusually low percentage strength accepted by the author as that of average breast milk, namely, one per cent. The author is very positive in his statements regarding the readiness with which the average child digests these mixtures and, in view of his large experience and close observation, his statements must be considered of much value.

The section on milk equipment for home modification is particularly practical. The same is true of the chapter devoted to the various details of modification and to the importance of securing fresh and uncontaminated milk. The section on infant foods, although not long, is one of the best that has been written upon that subject. The author holds that, tested by the unerring standard of the infant's natural food, no infant food fulfils the conditions required of a substitute. He believes them open to criticism in two particulars—chemical composition, and the source from which they are derived. It is a fact of great importance that milk is purely an animal food, of animal origin; most of these foods are of vegetable origin, and Nature has not endowed infants with digestive power to deal with excess of vegetable products.

The book will prove a useful household guide to infant feeding and will be an effective aid to the practitioner in prescribing diet. The one drawback in the latter case will be the

necessity of always having the book at hand. Although not extended, the work is a valuable contribution to the much discussed subject of infant feeding, as it is a record of actual experience of a very practical man.

Thomas Sydenham. By Joseph Frank Payne, M. D., Oxon. Longmans, Green & Co., New York.

This latest volume of the "Masters of Medicine" series, is a veritable glimpse of English thought, customs, and history in the seventeenth century, with a scientific man for a hero. Dr. John Brown speaks of Sydenham as "the prince of practical physicians, whose character is as beautiful and as genuinely English as his name." As portrayed in the pages of this delightful biography Sydenham whose name has always been a synonym for common sense and wisdom in the midst of quackery and ignorance is shown to be a man with a profound and classic education which he applied to the affairs of the nation. Always ahead of his time, and shrewd with the keenness of long and accurate observation he made many guesses at the truths which have only been revealed in the last quarter of the century, and also formulated many theories that to-day are as quaint and droll as they were advanced two hundred and fifty years ago. Certain it is with plague and smallpox and cholera constantly at hand to study Sydenham's observations are interesting seen in this day, and the book of his life, serving as it does, as the foreshadowing of many lines of modern medicine, is a romance and a history in medical literature.

Studies in the Physiology of Sex—The Evolution of Modesty, The Phenomena of Sexual Periodicity, Auto-Erotism, by Havelock Ellis. F. A. Davis Company, Philadelphia and Chicago.

The following passage from the preface of this book gives Dr. Ellis' point of view with regard to medical sexual matters very succinctly and completely. He says: "The omission of considerations of treatment or prevention (of pathological sexual conditions) at this stage is intentional. It may safely be said that in no other field of human activity is so vast an amount of strenuous, didactic morality founded on so slender a basis of fact. In most other departments of life we at least make a pretense of learning before we presume to teach. In the field of sex we content ourselves with the smallest and vaguest maximum of information, often ostentatiously second hand, usually unreliable. Before we can safely talk either of curing or preventing these manifestations we must know a great deal more than we know at present, regarding their distribution, etiology and symptomatology."

This passage strikes the keynote of the book. The author gives the result of his careful study of certain sexual phenomena that escape general notice. Sexual periodicity, for instance, with a consideration of the annual sexual rhythm and the tendency of the sexual impulse to become heightened in spring and autumn shows how much human and animal nature is in sympathy with the lower physical world around them.

There is an interesting appendix on the influence of menstruation on the position of women. Mr. Ellis discusses the influence of the monthly flow with its usual neurotic accompaniments as constituting certain important elements in the emotional atmosphere through which men habitually view women. In a second appendix Dr. F. H. Perry-Coste discusses sexual periodicity in men. He has shown by work on the rhythm of the pulse that pulse reading arranged in lunar monthly periods and averaged over several years displays a clear and sometimes a very strongly marked and symmetrical character. It would seem, then, that man has a monthly physiological period as well as woman, and the suggestion is made that this is of sexual origin.

SOME NOTES ON MEDICAL DIAGNOSIS.[1]

BY WM. N. BERKELEY, M.D.

OF NEW YORK:

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY; ASSISTANT IN MEDICINE, BELLEVUE UNIVERSITY MEDICAL COLLEGE.

AMONG Montaigne's pithy observations upon the function and work of the physician this passage occurs: The physician "hath neede of many parts, divers considerations, and severall circumstances to proportion his desseigne justly. . . God knowes how hard the knowledge of most of these parts is!"

Sorrowfully acquiescing in the general truth of the concluding sentiment, the practitioner of to-day may yet claim that since this critic's time, some progress has been made in solving the grievous problem of diagnosis. And I have thought that it would not be uninteresting to consider, in a very general way (1) with what spirit that problem should be met, and (2) what practical methods, and (3) what logical principles should be employed in its solution. The extent of the subject and the shortness of our time make it needless to add that the discussion will be fragmentary—a mere outline.

In respect of the spirit with which the medical adviser should come to the bed-side it appears idle to counsel freedom from prejudice. Yet prejudice is a snare which lies privily in wait for even the most experienced. Particularly in family practice, where we have known a patient for years and are in our own opinion perfectly acquainted with his constitutional vagaries, it seems a work of stupid supererogation to go over his organs afresh each time we are sent for. Yet I know of no other way in which to avoid grave error. The one hundredth attack of convulsions may prove to be uremic, even though the previous ninety and nine were certainly hysterical. The three patients first taken ill in the house may have had influenza, and yet the fourth with similar onset a few days later of fever and bronchitis may develop measles. The wise man will therefore come with an unbiased mind to the consideration of his cases and take each purely on its merits.

Disposing thus briefly of the first point, which is evident enough, we may at once take up the consideration of *methods*. This includes (1) the employment of instrumental and chemical aids, (2) and the general mode of procedure at the bed-side. This division is not a strict one, but it will serve our purpose and facilitate discussion.

Instruments of precision in diagnosis have become so valuable in recent times that no one can dispense with the commoner ones; and where the facts to be ascertained are of vital importance, no one *ought* to dispense with the rarer ones as well. The rhinoscope, laryngeal mirror, ear speculum, and ophthalmoscope ought to be familiarly in the hands of every general practitioner. A little serious determination to master them is promptly successful. Any physician should be able to see for himself whether aphonia is due to catarrh, tumor, or paralysis; or whether approaching blindness is consequent upon "choked disc" or albuminuric retinitis.

As to the stethoscope (into the numberless modifications of which there is no time to enter) there will of course be no dispute. But even here there are good and bad patterns; and the bad kinds predominate, with ill-fitting ear-pieces, tubes of capillary bore, and stenoses and dilatations enough to arrest more than half the vibrations of an ordinary cardiac murmur before it reaches the ear. Incidentally it may be observed that (with normal ears) any stethoscope through which a watch cannot be easily heard ten inches from the bell is a bad stethoscope.

The phonendoscope likewise deserves more attention than it has received. While doubtless a specialist's instrument it will well repay all the time the general physician can give it—and that not only in auscultation, but also in the modified method it allows of auscultatory percussion, commonly called "stroking." I have heard many physicians condemn the phonendoscope, who, when asked what success they had had with "stroking," answered with wide open eyes, that they had never heard of it. Some of the prejudice against the instrument may be due to the imperfect imitations of the original with which the market in the United States was glutted some years ago. A good imported instrument can always be had from the American agent in Philadelphia.

The alleged "trouble" in learning how to use it is not a legitimate argument for the man who wishes to be of the greatest possible use to his patients. It is not to be expected that one should, with the inventors, become skilful enough to stroke out the normal outlines of the middle lobe of the right lung. But for feeble sounds, such as the beginning pericardial rub, or the bronchial note over a feebly breathing solid lung, it will be found of great service. And for sensitive chest walls, in women or children, stroking can often be used without the patient's even suspecting what the doctor is doing.

At the same time no stethoscope of any kind should be used often enough to dull the sensitiveness of the bare ear on the bare chest; and

[1] Read before the Jenkins Medical Society of Yonkers and Mount Vernon, Dec. 13, 1900.

most observant physicians find out for themselves that the unassisted ear (perhaps from the help given by the cranial bones) will often reveal more of the internal condition of the thorax than the best stethoscope.

In respect of instruments of percussion, the pleximeter is not so popular here as abroad. The truth as to its value probably lies between the extremes of exclusive adoption and exclusive rejection. By means of the pleximeter one can map out the various areas of normal and pathological thoracic dulness with much more accuracy and detail than with the fingers. By using a small thin elastic plate of hard rubber one can percuss even over sunken supraclavicular spaces with entire ease. One should, however, train his unassisted fingers with equal care.

It would take us too far afield to do more than mention the sphygmomanometer and the sphygmograph. Both have ardent defenders. Without wishing to deprecate their employment, or to deny that they may in future be applied more practically than at present, it may be said that they have not thus far proved clinically so valuable as they are scientifically interesting.

With the microscope, however, no practising physician can be too familiar. Urinary sediments and sputum examinations of course every one does, but it is very little harder to diagnose one's own diphtheria cultures, make the search for malarial parasites, count the leucocytes in a case of suspected leucemia or leucocytosis, or look for the gonococcus. The diagnosis of tumors requires the additional equipment of a microtome, but if one can possibly find time for the work, he will be richly repaid and may be able unexpectedly to make more than one priceless contribution to pathology. The Widal test probably involves more technical experience than any but a laboratory man can usually command. There are, however, numberless places these days where a Widal test can be promptly done for a small fee; and a slide with a dry drop of blood is all that needs to be sent.

A student of mine recently said, when I proposed to teach him how to examine blood for the plasmodium malariæ, "Oh, I don't care whether I learn that or not; I can always find somebody to do it for me! I do not, however, conceive that we should do as *little* scientific work as we can, but as *much*.

Furthermore, the chemical examination of urine, cystic fluid, and stomach contents is left to the laboratories oftener than is needful, I think. The quantitative test for uric acid by Hopkins' method is something that any fairly well taught practitioner can do at home with a comparatively small chemical equipment. To diagnose "uric acid diathesis" without it, is mere self-stultification. To know how to determine, if nothing more, the presence or absence of free HCl in the stomach after a test meal is a great gain.

The Medical Director of an Insurance Company in New York tells of an amusing examination for insurance sent in by a provincial physician. In the blank lines for urinary analysis the medical man had written: "This urine throws down with *Fowler's solution* a cloud which I guess is sugar. I suggest that the urine be examined by a specialist." Over which we laugh. Yet many of us are sending to the specialists tests which after a little study are not a whit more difficult than the test for sugar in urine.

The question may be impatiently asked, Where is the time for all this? And, I concede, there are many physicians of unusual intellectual capacity who are weighed down by the responsibilities of a large practice; with whom lack of time is apparently a hopeless barrier. Yet we can point to brilliant examples—the first Austin Flint, Theodore Billroth, William Osler, Hilton Fagge, and a noble army of others—who did not and would not allow the exactions of practice to divert their minds from medicine on its scientific side. It is such men as these who have left their impress upon the science and the art of medicine for all time.

The second division in our discussion is, How shall we proceed at the bed-side?

To say that the successful practitioner is the methodical man seems another platitude. But, unlike the poet, the medical man is not "born," he is "made"; and it is only by patient continuance in methodical well-doing that he will ever work out his ultimate professional salvation. There is no royal road to diagnosis. The short cuts of the "snap" diagnostician, though, when successful, they may convert the unthinking, cannot but make the judicious grieve. The "Visiting" to one of the Children's hospitals in New York not long since heard a baby cough in the corner of the ward. To the wonder and admiration of the House Staff he called, "Bring that child here. It has a retropharyngeal abscess!" And on examination so it had. But we one and all know how rarely such work as this is safe. Patients often suffer with several diseases at once; even if one be externally manifest, there may be another, which it will perhaps tax our utmost capacity to discover. The solemn words addressed to his graduating class by a teacher of medicine known and admired by many of those here to-night are in point: "Gentlemen, you will make mistakes, of course; but your errors will arise far less often because you did not know than because you did not *take the trouble* to give your patients a faithful examination."

As to schemes of examination, they are numerous. Every writer of a text-book on Diagnosis thinks he must invent a new one. Most of them are reasonably good, the one essential being thoroughness. The practitioner should adopt or invent for himself one that is exhaustive, and then carefully habituate himself to it; for, as a wist moralist has remarked, we are safe in the possession of no virtue until its practice has become habitual.

The family and personal history of the patient should, of course, be elicited in minute detail. This is ordinarily, like the giving of ether, a task

left to the Junior in the Hospital. It ought not to be, for the value of the testimony so given may be critical at some crossing of the ways later on, and to estimate the veracity and intelligence of the patient or the patient's friends requires tact and experience. However, supposing it done as well as may be, we come to the *status præsens*.

The first general inspection should cover the scalp, face, trunk and extremities. The posture of the patient should be noted, the state of his nutrition, and the character of his breathing. Is he cyanosed, icteric, pallid, or flushed? Is he cachectic? Has he any local or general eruptions or scars? Are there any petechiæ on the arms or legs or trunk? He should be turned over and the back examined in the same way. Has he any dilated capillaries on the cheeks, nose or ears? Is there any dropsy? A practised eye will take in all these points one by one faster than they can be called over. We may note next the temperature and the rate of pulse and respiration, and observe the numerical ratios of the three to one another. When examining the radial pulse we should observe at the same time whether there is clubbing or cyanosis of the fingers, or any evidence of congenital deformity. A supernumerary digit may give the needed key to an anomalous cardiac condition, proving the latter to be a congenital malformation, it may be, rather an acquired lesion. Symmetrical onychia tells a solemn story; and, if it occurred acutely in childhood, the patient may be carrying the gnarled and twisted nails with him fifteen years later. One should not be content with counting the pulse and testing the regularity and tension, but should note if it have any of the "water-hammer" character, if it be dicrotic or sclerotic, if it be of the same size as and synchronous with the other radial artery, and if the carotids have a like character of pulsation. We thus rule out chances of deception from anatomical anomaly, and may get a valuable hint of aneurism. The epitrochlear and axillary lymph-nodes should be noticed on the way up the arm, then those on the neck and the groin. And this is the best time to test the deep and cutaneous nerve-reflexes.

Coming to the head, a rigid examination of all its features will be fruitful of information in a dozen ways. One thing often forgotten is observation of the so-called "signs of degeneracy." A good deal of nonsense has been published upon this subject in medical and scientific journals. Prof. Lombroso's results have been successfully questioned (see Ribot's Psychology of the Emotions) by numerous observers. All that concerns us in diagnosis is not, Are the features of the face degenerate or atavistic, but simply, are they ill-formed? Flat, projecting ears with adherent lobes, a prominent ("prognathous") jaw, an acute facial angle, thick lips, defects of the special senses—these things mean for the practical diagnostician that some of the viscera are likely to share in the malformation or at least to possess a lessened resisting power. A few slightly suspicious signs of tuberculous deposit in the apex of one lung appreciate in gravity if the external evidences of degeneracy are marked. Any one who works in a dispensary among tenement people may observe this over and over again.

The significance of sudden falling out of the hair is familiar. In babies the size of the fontanelles and degree of ossification should be observed. Next, the sense-organs should be taken up in order. The ear-drums should be examined with a speculum. If the patient's mind is clouded, or, if he is a child and has an acute pharyngitis, or adenoids, or any of the acute infectious diseases, the examination should be frequently repeated. A timely paracentesis will save the child's hearing in many cases where we now wait until the mother calls our attention to an otorrhea, and then find that occluded pus has damaged the sound-conducting media beyond remedy. German statistics some years ago showed that over 5 per cent. of all cases of acquired deafness in Germany were due to neglected ear-disease in the scarlatina of infancy.

The manifold relations of ocular disease to general pathology are well known. We should at least note whether there is exophthalmos, what is the size of the pupils, their reaction to light, the transparency of the cornea, and the movements of the muscles of the bulb. The ophthalmoscope and a lamp or candle will readily show what the condition of the retina and refractive media is; and the bright white perimacular spots of albuminuric retinitis, the pulsating central artery of aortic regurgitation, the choked disc of cerebral tumor, the presence of tubercles in the choroid—may throw a flood of light on a dark diagnosis. The nose, tongue and pharynx are rarely neglected by any one, but it should not be forgotten that marked syphilitic scars can sometimes be made out only with the laryngoscope. If hoarseness exist or any disorders be complained of which are referable to the larynx, it should be examined without fail.

After glancing at the thyroid and looking for pulsating areas in the neck we may go on to the chest. Of mensuration and succussion nothing need be said. As to inspection, as far as I have observed the work of physicians, it is unfortunately rather neglected. The osseous thorax should be first considered, the curves of the column, the outline and position of each of the spinous processes, the symmetry of the ribs, the presence of a "rosary," the "set" of the scapulæ on the back, the stooping of the shoulders, the depth, width and anterior-posterior diameter of the thorax, the relative size and prominence of the clavicles. Regarding these last it has been my experience that the right clavicle is generally thicker and more curved than the left. If this inequality be exaggerated, it will seriously dull percussion resonance over the right apex—especially in front. When the patient takes a deep breath, asthma and emphysema will often be disclosed in a moment by the slow expiratory collapse of the lung like a punctured balloon, by the fixation of the ribs in inspiration, the "barrel-thorax," and the tense-

ness of the sterno-mastoid and other accessory breathing muscles. If we are fortunate enough to make out the occasional line of dilated capillaries around the insertion of the diaphragm, we shall be perfectly secure in the same diagnosis without going a step farther. Kyphosis of the spine and rachitic angles in the ribs will often make a nearly flat percussion note even over normal lungs. These conditions should be all noticed carefully before percussion is begun. Litten's diaphragm phenomenon is often of value. A good light and an intelligent patient are the only prerequisites.

The state of the superficial veins of the thorax is something of which very little is said in the text-books. Chronic dry pleurisy with or without disease of the lung, if at all extensive, is apt to bring them into marked prominence. Locally dilated veins also result from chronic valvular disease, and adhesive pericarditis. In congenital pulmonary lesions I have found the surface veins just above the base of the heart often remarkably enlarged. A tumor of the pleura or mediastinum would probably have the same effect. The other visible signs of the circulatory function are equally important. Not only the apex-beat of the heart is often observable, but in mitral and pulmonary disease the action of the hypertrophied right ventricle can be often noticed in the 3d and 4th left spaces close to the sternum. The wavy impulse of dilation is familiar. The pulsating areas caused by aneurism are to be carefully sought for in front and all the way to the lumbar vertebræ behind. The intercostal spaces can be often counted with the eye, and the joint of the manubrium with the gladiolus made out without touching the chest with the fingers. The agitation made by a pulsating pleurisy may be visible. In deep breathing the meaning of entire absence of movement on one side or of a retracted apex needs no comment. The latter sign is often almost pathognomonic of tuberculosis.

Passing on to palpation there are many things too familiar to permit of notice. Palpation should be always done with one hand at a time. Vocal fremitus is far from the only kind one can feel, though there is only time to speak of pleuritic friction fremitus which is often present in dry pleurisy, and is easily made out with the tips of the fingers.

I have studied with unusual care the normal *degree of difference* between the vocal fremitus of the right and left lungs, and have been astonished, as time has passed on, to see how large the excess of vibration on the right side may sometimes be without other evidences of disease. It consequently is perhaps safe to say that no conclusion should be drawn from apparent variations of this excess unless other physical signs are confirmatory. Yet one valuable fact is secure; a *certain degree* of right-sided excess is invariable. If the left fremitus exceeds the right and we can exclude the presence of consolidation, of pleural thickening or a plugging or narrowing of one bronchus, the only remaining conclusion is that heart and liver (or at least the heart) are transposed. Twice in the last eighteen months I have been fortunate enough to prove this on cases of congenital inversion.

In respect of the endocardial murmurs it is a great mistake to use one's stethoscope before applying the fingers over the four points usually designated as points for auscultation. The vibrations of chronically inflamed valves are often palpable and sometimes more readily identified as thrills by the fingers than they are as murmurs by the ear. This is notably true of the familiar presystolic thrill which is pathognomonic of mitral obstruction and may be palpable before it becomes audible at all (Sansom). But the systolic mitral and pulmonary murmurs, and the diastolic and systolic aortic murmurs are also often palpable as thrills, and the sense of touch can be educated so highly to the perception of them that one finally may almost seem to have ears in the tips of his fingers. I believe that it would be a real contribution to physical diagnosis if some one in authority would give this fact its due emphasis.

One further incidental observation. The books rarely mention the anomalies of situation which the functionally normal apex may exhibit. There are several. The most important is the persistence of the infantile position, in which the apex, instead of occupying, as normally, the fifth interspace inside the mamillary line, lies in the *fourth space* behind or close to the nipple. In a majority of these cases the phenomenon has nothing whatever to do with pericardial effusion, as is sometimes stated. It is simply an anomaly, and is entirely consistent with normal cardiac function.

With respect to percussion the principal thing is to do it thoroughly, over every square inch of the lung. An anilin pencil should be used to mark the cardiac area and the upper level of hepatic dulness. The descent of the liver with a long breath should be carefully noted. If it does not descend, the lung is either in an advanced stage of emphysema or it is bound by adhesions. Either fact is vital. The degree of advancement of emphysema should be considered great if the pulmonary resonance extends, behind, as low as the second lumbar vertebra. This sign, if present, will differentiate any case of true emphysema from acute asthma (Leube). It has been noted already that over angles and unusual convexities of the ribs there will be a variably dull note, whatever the condition of the lung. I have seen experienced men deceived by this. Percussion in infants and small children is difficult and deceptive, owing to their irregularly contracting muscles and relatively large viscera. Proper discussion of it would require a separate paper. Unless one has large *postmortem* experience with babies he will do well always carefully to control his percussion by the other physical signs of disease before drawing a conclusion.

In regard to auscultation I must be very brief. In it, I think, physicians are as a rule much more competent and careful than in the other methods.

The great matter, as everywhere, is thoroughness. The breathing, the voice, the whisper, and the adventitious sounds should be systematically noted over all parts of both lungs. If this were done oftener, there would be fewer reports of bronchopneumonia without physical signs. For the average practitioner a safe rule as to cavities is that of Leube—Do not pronounce finally on a cavity till an amphoric echo can be heard, added to the cavernous sounds, or till elastic fibers can be found in the sputum. Other signs may deceive the very elect. Furthermore, for any, except a man with unusual experience, the *cracked-pot sound* is apt to be a mere delusion. Crackles over the margins of the lungs elicited by the first two or three deep breaths and then disappearing, are probably due to temporary collapse, and have no clinical significance.

What will be the ultimate value of the fluoroscope in diseases of the chest is not yet determined. Deep aneurisms and large hearts covered by emphysematous lungs are observable by the fluoroscope when every other means of detection fails.

Passing on to the abdomen, which offers far greater difficulties in exact diagnosis than the thorax, percussion and auscultation are of secondary value, inspection and palpation being our main reliance. After inspection, the abdominal viscera should be palpated in turn, spleen, liver, stomach, kidneys, cecum, appendix, sigmoid, uterus, bladder, testicles and hernial rings. Internal examination of the rectum and uterus may also be needful. No one should omit a single opportunity to palpate all kinds and conditions of abdomens, for nothing but an educated touch will be of any service to us, and to gain an educated touch requires years of practice. The patient should usually be on his back with knees drawn up, arms by the sides, mouth open and breath drawn deeply and regularly. The knee-chest position is sometimes serviceable. The lower margin of the normal liver is always palpable; no one should be content with mere percussion of it. The spleen can be touched by an experienced finger twenty times where a beginner can find it but once. The same is true of the kidneys, and in a less degree of the cecum and appendix. A normal adult spleen is not palpable; a palpable spleen indicates either displacement or enlargement—usually the latter, and it rarely fails to have some bearing on the diagnosis. Neither spleen nor kidneys ought ever to be overlooked. I was once told confidentially by a student of mine, who had been practising ten years and had returned to New York for further study, that he had never felt a kidney in his life till I showed him how to find one. This, I think, reflects as seriously on the medical colleges as it does on the unfortunate individual mentioned. A very little primary instruction is needed to teach medical graduates how to go systematically about the use of their fingers.

An instance or two of careless abdominal work may be briefly mentioned—instances which probably any of the gentlemen here can parallel in their own experience. A lady, long a victim of chronic nervous dyspepsia, came recently to a city man from out of town in a paroxysm of terror saying that her doctor had told her she has "a resistance" in the epigastric region which he thought to be gastric cancer. An examination readily showed that "the resistance" was only a localized contraction of one rectus. Another patient, a man of forty years, recently from Texas, came to me asking advice about a "swelling" in his abdomen. I found he had a monstrous spleen, from the history and the symptoms apparently an ague-cake. During the consultation he spoke of having just had his life insured in a downtown company. I asked how he got passed with such a tumor. His reply was, "Well, the doctor didn't examine my abdomen, and I wasn't going to tell him."

All such cases solemnly emphasize the importance not only of systematic examination of the abdomen in every case, but of losing no possible opportunity of training one's fingers on every patient whom we can persuade to let us make an abdominal examination.

All this done, we come to the urine, which should be examined as regularly as the heart and lungs. Many a physician seems to believe that though his patients are liable to cardiac or pulmonary disease, they bear a charmed life as far as their kidneys are concerned, and therefore a routine urinary analysis is mere waste of time. For these men, no lesson is so effectual as to have one or two of their patients die on their hands unexpectedly of diabetic coma or acute uremia—occurrences which the gentlemen present have heard of as often as I have. To test the reaction of the urine, the specific gravity, albumin, sugar, urea, and sediment, requires about ten minutes—often less; and the time is not wasted!

It is equally desirable to be sure that the blood is normal. In most cases the examination of an Ehrlich "triacid" stain will be enough, except where there is reasonable suspicion of the presence of parasites in the blood—the plasmodium, or the filaria. Whether a Widal test shall be made, or the sputum or stomach contents examined will depend upon the nature of the individual case and—in the phrase of the eminent Frenchman—"the brains of the physician."

The examination of the nervous system should not be forgotten, but it is a more special and technical subject than we have room for here.

When the facts have been ascertained and collected, the third and crucial part of the physician's task is reached—the diagnosis, the *judgment*, the assumption of a cause or causes which shall explain the varying and often perplexing phenomena which his examination has elicited.

Of the logical fallacies which beset this process on every hand time fails to speak. A word, however, may be added about one of the general logical laws on which diagnosis proceeds, the "Law of Parcimony." This law is that "causes are not to be multipled beyond necessity." Yet the rule is not to be too rigidly interpreted. For example,

enlarged axillary glands concurring with a tumor of the mamma would require us to suppose a malignant mammary growth with glandular metastasis. Yet after removal the growth may prove to be a fibroma and the glands tuberculous. So that we must choose not always the smaller number of causes, but the number of causes that explains the phenomena most satisfactorily. A "satisfactory" explanation is an indefinite term, but nevertheless as the years go by and our experience and study enlarge, we shall be able gradually to increase the number of our "satisfactory" diagnoses, and eliminate the errors of our earlier years. Eternal vigilance is the price. A good rule for the medical man is to send his patients to the surgeon or the *postmortem* room with a *written diagnosis*. He will be often enough laughed at; yet he will gain enough to compensate for the ridicule. And he may console himself by remembering that the surgeons and pathologists, for all their scorn, have fields of labor of their own where they too, like us, are groping in darkness, and only by slow degrees feeling their way to the light.

121 East 26th Street.

THE MINERAL WATERS OF MT. CLEMENS, MICHIGAN, AS VIEWED AND COMPARED WITH THOSE OF EUROPEAN WATERING PLACES.

BY RICHARD LEUSCHNER, M.D.,
OF MT. CLEMENS, MICH.;
MEDICAL DIRECTOR, ORIGINAL SPRINGS BATH HOUSE.

During my trip to Europe last year, a considerable portion of my leisure time was spent in the more prominent and renowned watering places of Germany and Austria, with a view of investigating the merits and medicinal virtues of their respective waters, laying special stress upon their study from a chemical, physiological and therapeutic standpoint, and devoting part of my time in obtaining some comprehension of the auxiliary methods in vogue at the various resorts, principally those pertaining to diet and hygiene, etc., in order to compare them with the baths and the methods employed here at Mt. Clemens, and, if practicable, to apply such innovations and foreign measures to the best advantage in fostering and strengthening the merits and reputation of our own salubrious sulpho-salines.

It is universally conceded by medical authorities that the minute and systematic attention accorded to these particular branches of medicine, to physical culture, and to detail work in general, as exemplified in the watering places of Europe, has contributed in no small measure to their fame as health resorts. Having this object in mind and such a task before me, sojourns of longer or shorter duration were inaugurated at Carlsbad, Marienbad, Franzensbad, Elster, Kissingen, Wildbad, Baden-Baden, Homburg, Wiesbaden, Kreuznach, Nauheim, Wildungen, Oeynhausen and Aix-la-Chapelle.

A few of the less important ones were also included, namely, Soden, Ems, Schwalbach, etc. Prolonged stays were made at Carlsbad, Marienbad, Elster and Franzensbad, the longest, however, in Kissingen, Nauheim. Kreuznach, Aix-la-Chapelle, Wildbad and Oeynhausen, some of those cities and towns exhibiting more interest to me on account of their mineral waters, showing an analysis resembling in some respects those of Mt. Clemens, consequently bringing them nearer to or even within the same classification as our own sulpho-salines. At the same time more importance was attached to these health resorts and more attention devoted to them because their respective waters, being principally administered externally in the different forms of baths, owe their fame and reputation to the successful treatment of almost all metabolic disturbances and ailments of the human system, including especially some of those diseases, *i.e.*, rheumatism, gout, skin diseases, diseases of women, catarrhal affections, etc., the cure of which brought prominence to Mt. Clemens and made this resort a formidable competitor. Only a few days of observation and study were given to the more fashionable resorts, comprising Homburg, Wiesbaden, Baden-Baden, Ems, Schwalbach, etc., the throng of "Passanten" and "Curgaeste," seeking these idyllic spots, probably more for enjoyment and recreation, than to indulge in a systematic cure by the application of their effective springs. In all of the resorts mentioned the first thing that impressed me as being most rational and praiseworthy was the observance of a distinct system introduced by the medical fraternity and approved by the authorities in charge of the various springs; and it also occurred to me that, while physicians considered the mineral waters the chief medicinal agent, they did not rely exclusively on the efficacy of the springs, but paid considerable attention to promoting and explaining the feasibility of auxiliary methods and details. The careful physical examination of the patient, of the blood, urine, and, if necessary, the fecal matter; the prescribing of dietary and hygienic regulations, and the absolute refusal to allow any one the privileges of a "curgast" without the examination and consent of a physician, made apparent the exactness of the work. The inhabitants of the different resorts, old and young, inspired by the merit of the waters and success accomplished, seem to idolize the springs and consider them sacred. They ostensibly have perfect faith and confidence in the authorities and physicians entrusted with the management and guidance, who are watching over the destinies of their cities or towns, and all are united in urging visitors and patients to be obedient to the instructions as laid down by the doctors, lest the cure might

not be as successful as otherwise; and therein lies in a great measure the scientific and commercial prosperity of the European resort. This careful observance of method and detail was particularly noticed in Carlsbad, Nauheim, Kissingen, Marienbad and Oeynhausen.

In the majority of our American health resorts, very little attention is seemingly attached to the importance of auxiliary methods and detailed application. Everybody appears to be enthusiastic and satisfied, commercially and possibly scientifically, with the results so far achieved. American patients in European resorts are models in themselves. The physicians and authorities there have them well in hand, in consequence of their admirable system. American patients in American resorts would be quite as exemplary but for the reason of the existence of unsatisfactory methods or no system whatsoever.

No matter how exact the American physician may be in the examination of his patients and in explaining the importance of dietary, hygienic and other precautions, patients are very apt to transgress and unconsciously break away from the rules and advice given. The whole environment, including the attitude of the laity, leads them to the impression that all that is necessary is to jump into a bathtub or drink enough of the water and Providence will watch over the rest. Should anything unforseen happen afterward, the blame is naturally and quickly attributed to the supposed inefficiency of the waters.

In all probabilities, some of the springs, Mt. Clemens included, would have risen to a higher plane of recognition and earned their scientific standing and success, with the attending prestige in the eyes of the medical world even in a much shorter space of time than they already have, if, at the very inception of the discovery of the therapeutic value, more attention had been accorded the investigation and study of the physiological action and effect and chemical composition of their waters. And, if in addition, the proper steps had been observed in the adoption of a certain subsidiary system pertaining to diet, hygiene, etc., the percentage of patronage and cures would have been vastly increased. What would have been the effect medically, to say nothing about its financial aspects, upon Carlsbad, Nauheim, and all other European resorts of note, if, after their discovery and the introduction of their waters to the world as curative agents, empiricism and commercialism had been allowed to reign indiscriminately, slaughtering and burying all attempts at scientific progress in consequence of a faulty organization and a reluctance and apathy on the part of the authorities and citizens? The result would have been undoubtedly a scientific lethargy, to awaken from which would have presented quite a problem and a difficult if not impossible task. In late years, Mt. Clemens, taking cognizance of the advantages of medical research, has steadily been emerging from a chaos of empirical application, adapting itself to the more modern methods of balneo-therapy, diet, and hygiene, commensurate with the evolution of scientific and commercial progress. This is demonstrated by the yearly additions of new hotels, bathhouses, etc., giving Mt. Clemens renewed hope for further prosperity in the new century. Let us look briefly into the causes that brought distinction and fame to the health resorts of Germany and Austria, and endeavor to compare the same with Mt. Clemens.

Carlsbad was discovered on the occasion of a hunting trip of Emperor Charles IV.—is well known and has been famed for centuries for its healing springs of undoubted medicinal merit. It owes its therapeutic success as a remedial agent chiefly to the systematic ingestion of its thermal waters into the system. Its waters are drunk in prescribed quantities, at specified intervals and at certain temperature, and they are assisted by the application of the different forms of baths, *i.e.*, moorbäder, mineral, electric, sand and gas baths, aided by adhering strictly to a dietary regimen, based upon physiological and chemical observation, individualized and made suitable to the condition of the respective patient. The dreaded and wrongly heralded terrible restrictions pertaining to the cuisine are a myth.

In addition to the auxiliaries, bath and diet, the hygienic resources for the necessary exercise and rest to the mind and body are amply supplied naturally by the beautiful surrounding country, its fine scenery, forest-topped mountains and an atmosphere permeated with ozone; artificially by splendid drives, walks, and parks, gymnastic and electrical institutes (Zander), etc., etc., and artistically by a magnificent orchestra sending forth strains of soothing and enchanting music, with an occasional terpsichorean delight at the casino and theater. The sixteen different thermal springs of Carlsbad of which the Sprüdel and Mühlbrunnen rank first, are the main representatives of the alkalo-saline mineral waters, containing principally sulphate of sodium and potassium, chloride of sodium, carbonate of lithium, strontium, sodium, calcium, magnesium, iron and manganese, some carbonic acid gas, etc., ranging in temperature from 95° to 162° F., with a faint saline taste. They act physiologically by their warmth as they come into immediate contact with the mucous membrane of the stomach and alimentary canal. They thus allay pains and spasms of these organs, stimulate the circulation and glandular secretions, increase the activity of the digestive organs, and change the condition of the blood and derivative secretions (urine, bile, etc.,) by increasing its alkalinity. In consequence it is indicated and recommended in the

treatment of diseases of the stomach, intestines, spleen, kidneys, and all metabolic disturbances, its fame having spread, however, through its successful treatment of severe liver complications.

Next to Carlsbad, Marienbad in Bohemia enjoys a very creditable reputation, especially in the treatment of obesity, fatty infiltrations of the liver and heart, obstruction of the portal circulation, habitual constipation, chronic catarrhal conditions of the stomach and intestines, etc., its physiological action being more intense than the waters of Carlsbad. In their chemical composition they resemble the Carlsbad waters, are doubly stronger and have a mean temperature of about 50° F. Franzensbad in Bohemia and Elster in Saxony are similar to Marienbad, and are equipped like Carlsbad and Marienbad with all the necessary auxiliaries and methods conducive to the health and welfare of an increasing patronage. Kissingen in Bavaria is also a powerful saline of remedial merit, and is frequented by many patients from all parts of Europe on account of its efficacy in dyspeptic conditions, etc., and has received considerable notoriety through the yearly visits of the late Ex-Chancellor of the German Empire, Fuerst Bismark. Wildbad in Württemberg, a thermal saline, is recommended principally in muscular rheumatism, neuralgias, and as an after-treatment in aiding tedious convalescence, etc. Wildungen in Hessen-Nassau derives its large patronage through the splendid results achieved principally in the successful treatment of diseases of the urinary tract.

Another health resort, favorably known for hundreds of years within the borders of its own land as a healing spring in numerous diseases, has suddenly sprung into significance and gained meritorious recognition throughout the civilized world, because of its carbonated thermal saline waters in balneo-therapeutic application in the eminently satisfactory treatment and successful relief of almost all pathological or functional derangements of the heart, aided by the administration of the famous auxiliary method known as resistance movements, Oertel's "Terrain Curen" and other hygienic, therapeutic and dietetic measures. I refer to Nauheim in Hessen-Darmstadt, near Frankfort on the Main. To the untiring efforts of Drs. Schott, Bode, Grödel and others, in chemical and physiological work upon the waters of their various springs, belong principally the credit in presenting to science the bath system adopted and now in operation at Nauheim. Physiologically, Nauheim water possesses powerful stimulating properties for the nervous and circulatory systems, and eliminates old infiltrations, etc., through its lymphagogic and cholagogic action. Hundreds of Americans and English visit Nauheim each year, not alone for the relief of heart complications, but also for nervous affections, female disorders, rheumatism, gout, etc. Kreuznach and Oeynhausen in Germany are also saline springs of note and Aix-la-Chapelle fastened its hold on the medical fraternity years ago through its successful achievements in syphilitic affections.

In attempting to draw a comparison of the chemical analyses, physiological action and therapeutic efficacy of the European resorts to which I have briefly referred in the foregoing remarks, with those of our own springs, one is confronted with a difficult problem and must admit that it is quite impossible to judge them correctly from the same standpoint or place these remedial agents in the same category or classification. All show a distinct analytical composition; some claim a physiological supremacy and others are again held to be therapeutically superior in the various manifestations of disease. Mt. Clemens also is blessed to a certain degree with these well-defined characteristics pertaining to analytical, physiological and therapeutic qualifications, and boasts of its peculiarily unique balneotherapeutic merit and success. None of the waters mentioned resemble ours very closely. Some show an analogy, inasmuch as they contain chemical products of the same composition, but not one can present such an admirable array of physiological and chemical strength as the wells of this leading bath town of Michigan give up from the bowels of the earth. Many of these springs are classified as thermal salines with or without CO_2; others come under the categories of the cold alkali salines; again we find in others sulphur combined with alkalies in the form of different salts as the chief agents. Then, again, sulphuretted hydrogen in conjunction with various salts poses as the paramount factor and one or two of the waters display evidence of iodine and bromine combinations. If we should take the waters of Aix-la-Chapelle, Wildbad, Kreuznach, Oeynhausen and Nauheim and mix them together, this aqueous coalition would possibly present analytically most of the elements and ingredients thus far discovered and represented in the waters of Mt. Clemens, the ratio of percentage, however, favoring the American spring by a proportion of 23 to 5. I doubt if there is to-day a spring or well, in existence or operation that can display such a combination of valuable chemical elements in the form of various salts, etc., and in such amounts as do the waters constituting our sulpho-bromo-iodo-salines.

The thorough investigation of these mineral waters conducted in recent years by Mr. John Meyer, chemist at Mt. Clemens, disclosed the presence of most rare and valuable elements known in the science of chemistry and are partly as follows: Sodium, calcium, magnesium, chlorine, iodine, bromine, potassium, lithium, rubidium, caesium, strontium, boron, aluminum, silicon, iron, manganese, sulphur-

trioxide, and gases of hydrogen-sulphide, carbon-dioxide, and traces of hydrogen-selenide. All these named elements present themselves in the proper quantities to form a combination of their respective salts, of which one of our mineral baths contains about one hundred and twenty-five pounds in solution. Physiologically it is claimed for the waters of the different European resorts that they are exceedingly effective in bringing about the necessary metabolism in the system by stimulating the glandular secretions, hastening cell proliferation, etc., and eliminating waste material, by the process of absorption. It is with perfect justification that they make the assertion. Not alone do their waters, applied externally, impart to the skin the warmth and mechanical stimulus of an ordinary water bath, but also a chemical as well as an electrical one, due to the ionic condition of the mineral ingredients, the carbonic acid, and sulphuretted hydrogen, producing reflex modification of the changes of material in the system.

On account of the high concentration of our own mineral waters, here at Mt. Clemens, holding in solution the various salts, proportionately as found in the human blood (namely, chloride of sodium, chloride of calcium, chloride of potassium, etc.), besides the powerful alterative effect attributed to and produced by the sulphur, iodine, and bromine they contain, and our methods of administering them, we claim practically the same as is claimed for the European resorts; in addition, however, we emphasize the fact that the action is more pronounced and speedy, and the results, consequently more satisfactory.

Writers and physiologists for a long time fostered the idea that no ingredients were absorbed through the skin during the bath, but this teaching is shown to be false by the latest researches of such eminent clinicians and physiologists as Wittich, Gutman, Wolkenstein, and Chernszwesky. They say in substance that the skin is permeable for watery as well as alcoholic solutions, being more energetic, however, with increased temperature. The absorption is carried on in different ways; by diffusion, through the blood-vessels, and through the lymphatic system. Patients will invariably speak of a peculiar salty taste in their mouths, some hours after the completion of a bath here at Mt. Clemens, and experiments by our chemist upon the urine of patients who have completed one week's daily application of our mineral baths with the customary massage, and who have not taken any medication whatever during the time, revealed the remarkable fact of the presence of distinct traces of iodine and bromine. This demonstrates beyond a doubt that absorption has taken place through the skin and resorption into the general circulation. The concentration of the Mt. Clemens salines and the amount of salt substance they hold in solution are certainly not without a distinctive value. When a body is immersed in one of our mineral baths the skin separates two salt solutions of unequal concentration, one being the blood serum, and the other the mineral water proper, and, according to the physical law of osmosis, and ionic action and properties of the molecules, and equalization of the two solutions will be brought about or at least attempted. While one must admit that the skin prevents a direct transudation, an approximation of the two solutions is at least attained, the secretions of the body (blood and intercellular liquids), enter more energetically into the course toward the periphery of the body, thereby establishing an increased lymph-current to those parts. This is in direct evidence that the quantity of the various salts held in solution in this mineral water is of very great importance regardless of the absorption. The more concentrated the mineral water for our purpose, the more energetic and pronounced these phenomena will be in manifesting themselves. Recently, the old theory of value of certain salts, especially common salt, for the maintenance of health and life has been revived by a great many scientists, some going so far as to say that chloride of sodium in conjunction with chloride of calcium and chloride of potassium constitute the vital energy of the blood and its circulation, and are the causative factors in controlling the heart beats. The importance of these salts for the life and function of the blood is conclusive; and in all metabolic disturbances of the human system, including infection, autointoxication, nervous, anemic, and toxemic disorders, we find a deficiency of these particular salts. To the absorption of these saline ingredients, and alterative action of the sulphur, iodine and bromine, etc., ridding the system of waste material, and to the stimulation of the nervous and circulatory system by the application of our mineral waters in the form of baths, the balneo-therapeutic value and efficacy of the Mt. Clemens sulpho-iodo-bromo-salines have been amply established. This is especially noticeable in recent years and is sufficiently demonstrated by the increasing patronage of those who seek relief, principally from rheumatic conditions in all its forms, including acute and chronic, gout, arthritis deformans, skin diseases, syphilitic manifestations; diseases of the nervous system; catarrhal conditions of the alimentary canal, etc., diabetes mellitus and insipidus, tedious convalescence, etc. In diseases of women the mineral waters applied in the form of vaginal douches in consequence of traces of selenide of hydrogen, etc., have shown themselves to be indispensable in catarrhal and other conditions of the female genital tract.

The views herein expressed, relative to the merits and conditions governing European resorts and Mt. Clemens, are based on incon-

trovertible facts as they exist. German, Austrian and European resorts, in general, enjoy the distinction of being conducted on a scientific basis, while at American watering places we are regretfully obliged to admit that there is as yet ground for improvement in this respect.

THE TREATMENT OF CHRONIC PURULENT OTITIS MEDIA.[1]

BY JAMES F. M'KERNON, M.D.,
OF NEW YORK;
AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

In treating a case of chronic purulent otitis media we should have three objects in view, first, the cure of the otorrhea; second, the improvement of the hearing, and, third, the relief of the distressing subjective sounds, if present.

In the treatment of the discharge the first cardinal principle is cleanliness, and this can be accomplished in one of two ways. If but little discharge be present, and the patient seen frequently by the surgeon, the existing discharge can easily be removed by mopping the parts with sterilized cotton, wound on a cotton-carrier. After the field has been gone over in this way it should be thoroughly cleansed with some comparatively strong non-irritating germicide or disinfectant, and one which the writer has found beneficial is the following

℞ Boric acid.....gr. xx
Sol. hydgrarg. bichlor. 1-1,000..℥ij
Spir. vini rect. ad. oz. 1.....℥j

The parts are thoroughly cleansed with this solution, and any granular surface is touched with a small cotton-tipped probe, dipped in silver nitrate, of a strength ranging from 20 to 240 grains to the ounce of distilled water. This will, in a large number of cases, so stimulate these structures, that by using such treatment two or three times a week, a cure will speedily follow. If, on the other hand, the discharge is profuse, then the patient, or whoever is to care for him, must be taught the proper method of syringing the ear and the treatment carried on by irrigation. Usually a hard rubber ear syringe with a blunt point or nozzle, holding an ounce of fluid, should be used. In the case of young children it is desirable that the syringe be of soft rubber, in order not to irritate the meatus or canal, and in shape should be like a round bulb, with a long drawn out point, through which the fluid passes on its way from the chamber of the syringe to the canal.

A point to be remembered in syringing the ear, and also to be impressed upon the patient or nurse, is to give instructions in all adult cases to grasp the auricle gently between the thumb and fingers of the left hand and draw it upward, backward, and a little outward, thus straightening the meatus and cartilaginous canal, and bringing it on a line with the osseous canal. Otherwise, when we use the syringe, we shall be directing the stream of fluid against the side of the canal wall instead of directly into the lumen of the passage, as drawing the auricle in the manner described will overcome the irregularity at the opening of the canal and allow the nozzle of the syringe to pass into the meatus deeply, with its tip directed downward and forward. In syringing the ears of a child under three years of age, the auricle should be drawn outward and downward, as this position best aids us to overcome the natural curve of the canal at that age. The frequency of irrigation will depend largely upon the character and quantity of the discharge, and at no time must it be allowed to accumulate to any extent in the auditory canal. In an ordinary adult case, it should be cleansed every three or four hours at first, and as the discharge begins to lessen, then diminish the frequency of irrigation to three times a day, or once or twice a day, and later even to every second or third day. In a child it will be necessary to irrigate more frequently on account of the smallness of the canal and the tendency of the walls at the meatus to lie in contact, thus driving back the secretion. In these cases we should irrigate as frequently as every two hours until we notice a gradual lessening of the discharge, and from this point on diminish the frequency to every three, four, or six hours, depending upon the quantity of the discharge that presents itself each day. It is always well to bear in mind that an ear should be irrigated only frequently enough to keep the discharge from accumulating in the canal, as too frequent irrigation serves to soften, make flabby, and lessen the integrity of the parts, thus prolonging the disease. Only a small amount of force should be used in irrigating an ear, whether the case be a child or adult, and we should never use a cold solution, but one tepid, or slightly warmer, depending upon the amount of comfort given to the patient. The quantity to be used at each irrigation varies anywhere from a quarter of a pint to a pint. Rarely is it necessary at one sitting to use more than the maximum quantity given above.

If irrigation produces, as it sometimes does, disagreeable symptoms, as pain, vertigo, or nausea, and these persist, then no matter how profuse the existing discharge, we must cease the irrigation and remove the discharge by frequent mopping and cleansing with cotton. In all cases after irrigation, it is desirable to dry the deeper parts as well as the meatus with cotton.

The various solutions used for syringing the ear have been legion, but only those will be mentioned which the writer has found of value from a clinical standpoint.

[1] Read before the annual meeting of the Medical Society of the State of New York, Albany, Jan. 29, 1901.

A solution of bichloride of mercury, in strength ranging from 1-2,000 to 1-5,000 in boiled water, is the solution most used, and the one from which we obtain the best results at the present time. A solution of value, and one largely used to-day by the general practitioner, is that of boric acid of the strength of 20 grains to an ounce of boiled water. As a cleansing solution it answers the purpose very well, but taken from a disinfecting or germicidal standpoint, it leaves much to be desired.

A solution of carbolic acid in sterilized water of the strength of one or two per cent. was formerly used. In obstinate cases, a weak solution of formaldehyde, 1-1,000, is often of service, owing to its active germicidal properties, but even in this strength it has to be discontinued many times, owing to its irritating qualities, and if continued should be used in a much weaker form. A solution of permanganate of potassium, half a dram of the liq. potass. permanganas in from four to six ounces of sterilized water, is often used to abate the discharge, on account of its strong disinfecting properties, and at the same time it acts as an excellent deodorizer when we have a foul smelling discharge to treat.

When a certain amount of exfoliated epithelium is found in the discharge, accompanied by a roughened condition of the canal walls and a roughened and excoriated condition of the meatus, we have found of the utmost value a one-eighth per cent. alcoholic solution of salicylic acid of the strength of from one to two drams of the solution in four ounces of sterilized water, the acid here having a marked healing effect on the excoriated tissue. For simple cleansing purposes, a tepid solution of plain sterilized water will be all that is needed.

In a few of the cases coming under our observation, where the so-called irrigation treatment has been used, they become perceptibly worse, and the discharge increases instead of lessening. When this occurs, the patient, or whoever is caring for the case, must systematically use the dry treatment just spoken of above, in order to obtain the beneficial results desired.

In order to save the patient's clothing while using the irrigation method, we should always have held by the patient beneath the ear, a kidney-shaped hard rubber or agate ware basin, to catch the discharge coming from the canal. These are easily obtained and come in all sizes. As soon as the discharge begins to lessen perceptibly the congestion and swelling gradually subside and the structures slowly regain their normal appearance.

In all cases when treatment is begun, a thorough investigation of the upper respiratory tract should be made, and, when these structures are found involved in a catarrhal process, we should direct our treatment to the cure of these pathological conditions as well as caring for the ear alone, for, if these conditions be neglected, we may temporarily help the aural conditions, but exacerbations will occur from time to time, owing to the lack of proper treatment in the nose and nasopharynx; especially should we always search for any lymphoid hypertrophies, and if found their removal is imperative at once, as well as the removal of any other obstructive condition which interferes with a normal nasopharyngeal function.

When the drum membrane has been destroyed over a considerable area and we find the inner tympanic wall exposed and presenting a mucous surface that is swollen, congested, and covered with mucus, or only slightly moist, then we must stimulate this surface by applying solutions to the mucous membrane lining the internal tympanic wall. The solution giving the best results is one of silver nitrate, applied in varying strengths, beginning with a weak solution, as ten grains to the ounce of distilled water and increasing this strength, as indications arise, to 240 grains to the ounce, or even as high as 360 grains to the ounce, when a rapid effect is desired.

A point of value in applying the silver solution may be mentioned here, and that is, care should be taken not to touch any portions of the canal walls or other parts of the tympanum except the particular area we wish to stimulate, and this can be accomplished easily by exercising a little care in preparing the cotton tipped probe. It should not be large or bulky, but small, having only the tip dipped into the solution, and all residue pressed from even this before introducing it, as otherwise the normal tissue will be smeared over and an excessive irritation caused by its coming in contact with such tissues. Other solutions used with beneficial results are varying strengths of the zinc and copper salts, of the latter, usually a two per cent. solution is the one most frequently used.

As the discharge becomes lessened and the patient is seen less frequently, a solution to be used at home should be given, composed of the following ingredients:

℞ Boric acid .....gr. xx.
Sol. hydrarg. bichlor, 1-1,000.....ʒij.
Absolute alcohol to make.....ʒj

Five or ten drops of this solution placed in the ear twice a day at first, then later once a day, and, as the cause for stimulation becomes less, every second day, will act admirably, not only as a stimulant, on account of its alcoholic properties, but as an antiseptic, due to the presence of the boric acid and bichloride solution in preventing the formation of further granulation tissue. The method of placing this solution in the ear can be accomplished easily, by one of two ways. Either a dropper can be used, or the requisite number of drops can be placed in a small spoon, then warmed, if desired, and poured into the auditory canal,

the head in each instance being held well over to the opposite side. If any residue remains after one or two minutes, it can be removed by turning the head in an opposite direction thus allowing the liquid to escape.

When the discharge is markedly persistent and the above applications fail to bring about a satisfactory result, the writer has found of benefit the use of the so-called Powell's solution, which consists of the application to the diseased surface of a solution of pure carbolic acid. This is allowed to run into the canal, the head being held in a horizontal position until the auditory canal is nearly filled. It is retained in this position from thirty to sixty seconds, and then the canal is quickly syringed with a solution of absolute alcohol. In this way the alcohol counteracts any escharotic action which the carbolic acid would have upon the normal tissues, and the diseased parts are stimulated and cleansed at the same time. By this treatment excellent results are obtained in many cases that would not yield to the ordinary methods in vogue.

A question may be asked as to the amount of pain involved in this procedure. It is very slight, as the carbolic acid is an anesthetic and the quick after-application of the alcohol causes the patient to complain only of the ordinary stinging sensation usually experienced, in a mild degree, upon the application of this liquid.

In all cases under treatment we should, after thorough cleansing of the canal, direct the patient to perform inflation by the Valsalva method, so as to drive out from the middle ear any retained secretion that may be present. Should they be unable to do this, then gentle inflation by means of the catheter should be practised, and the secretion thus displaced be removed before our final application is made to the surface to be stimulated.

The practice of instilling oil of any kind into the canal should not be countenanced, as it forms a media for the development of vegetable fungi of various kinds, and when once these conditions form along the canal they are exceedingly irritating and difficult of a rapid cure.

As to the use of hydrogen peroxide in the auditory canal of a patient suffering from chronic purulent otitis, there is a wide diversity of opinion. Some authorities report most brilliant results from its use, both by syringing the canal freely with it, and also instilling it into the canal, claiming when so used it cleans out the small cavities by displacing retained secretions, which otherwise would not appear without the use of this agent. I believe, however, we have other means at our command that will do the work quite as well, without exposing the patient to the risk of displacing and driving backward through the *aditus ad antrum* this retained secretion into the mastoid antrum, and thus exciting an inflammation of this structure by the infection contained in the displaced secretion, for it is very plain to be seen that such secretion, when displaced, can travel this path quite as easily as any other, and the writer has seen several cases of purulent otitis under treatment, doing fairly well, when it was thought advisable to use this fluid, to hasten matters if possible. Where no sign of mastoid involvement had previously existed, under the use of this fluid, a distinct mastoiditis developed, and in four cases the mastoid had to be opened. So, from observation and personal experience, I am opposed to its use. Under no circumstance or conditions should we in this disease either early or late put a large quantity of powder in the canal and allow it to remain there, for it becomes moistened and later forms a crust, thus preventing what we wish to avoid, namely, a damming backward of the secretion, and the practice of supplying a patient with a quantity of powder to use by himself cannot be too strongly urged against, as many times he will use it and drive the secretion backward by crusts forming firmly over the point of perforation, and this acts as a barrier to the future drainage of the middle ear, as well as subjecting the patient to the danger of mastoid and other intercranial involvement. After the discharge has been reduced to a minimum amount, so that it only moistens the part, then we can use with much advantage some of the many antiseptic and astringent powders by insufflating a small quantity over the moistened area. The powders more commonly used here are: Boric acid, aristol, acetanilid, nosophen, zinc oxide, iodol and alum. Iodoform was formerly used extensively, but has been largely discontinued, as it is very unpleasant for both the patient and surgeon, on account of its peculiar odor, and it often gives rise to a most distressing dermatitis. Dermatol has also been used, but possesses no particular curative effects. In many cases where the discharge is intractable and comes from the attic region, the use of the intratympanic syringe is of the greatest value, as by its use we can introduce solution of various strengths, upward and backward, beyond the point of vision. The writer has used a small glass instrument of varying sizes, with short or long tip and broad end fitted closely with a rubber similar to that of the pipette. These little glass pipettes are made in almost any size and the tip can be made at any angle one wishes. They are easily handled, neat, clean, inexpensive and contain for treatment all the way from one to twenty drops of the fluid which is usually a solution of silver nitrate.

In cases where we find a large amount of granulation tissue present, we proceed to destroy this after first cleansing the canal and area to be destroyed. If the granulations are

only moderately large we can easily destroy them by means of chemical agents. The two agents of this character most used are silver nitrate and chromic acid. The surface to be cauterized is first dried and then upon a metal probe a bead of either of the above agents is fused and applied carefully to the granular area. Care should be taken not to smear these agents over adjacent parts, and all excess or residue should be mopped up with a cotton pledget. The actual cautery has been recommended as admirable for the destruction of these granulations, but its use here is altogether too difficult of application when we have at hand other means equally as good and much easier to apply.

After cleansing the area to be cauterized we should apply to the granular surface about to be destroyed a solution of cocaine hydrochlorate, of a strength from five to ten per cent. This application can be made by soaking a small pledget of cotton in the cocaine and carrying it with the forceps directly against the surface we wish to anesthetize, or we can apply it by means of a cotton-tipped probe, and hold it against the surface for a moment or two until the anesthetic effect has taken place.

If this preliminary be carried out in these cases, there will be but little or no pain experienced by the patient during the destruction of this exuberant tissue, and this in itself is a factor to be taken into consideration, for no one likes to suffer pain when it can be so easily avoided. When the granulations are larger and polypoid in character, their removal is best effected by means of the wire snare. The loop of the wire is passed over the growth and carried backward and inward to its attachment and the growth is cut off in this way by the successive turning or screwing of the thumb-piece of the snare, thus tightening at each turn the loop of wire surrounding the growth.

As a more rapid means of removal, a sharp curette is preferred, and this can be passed quickly into the canal at the side or beneath the growth and carried backward to its point of attachment, which is usually a rather firm pedicle. When this point is reached, the curette is raised and manipulated so as to partially twist the pedicle around the shank of the curette, having the sharp curve of the instrument rest upon the superior or upper surface of the pedicle. The curette is then pressed inward against the surface from which the growth springs, the pedicle is severed close to its attachment, and the growth is removed at the same time the instrument is withdrawn. Cocaine should always be used previous to their removal, in order to relieve the patient of as much pain as possible. An adjunct of great value, at our command in the removal of these growths, is an application to them (and particularly at their base) of a solution of suprarenal capsule. Following is the formula used by the writer:

℞ Adrenals (Armour Desic.).....5i
Acid boric ..... grs. xvi
Aq. cinnamomi.....5iv
Aq. camphoræ cal.....5i
Aq. dist. cal., q. s. ad.....5ii
M. Macerate for four hours, filter.

The use of this solution enables us to remove large growths, and what would otherwise be a bloody operative case is rendered practically bloodless by the use of this fluid. It should remain in contact with the tissue to be removed for at least ten or fifteen minutes prior to the operation. Our after-treatment is also greatly facilitated by its use, and now we are enabled to cauterize the base left by removal of the growth without continually going over the surface for several minutes with cotton pledgets, trying to staunch the blow flow before we apply our cauterization. Many times, by the old method of removal, without the use of the suprarenal extract, the cauterization of the base had to be left for a second sitting on account of the free hemorrhage existing.

For the first twenty-four hours after the removal of such a growth, it is well to pack the canal loosely with a strip of plain sterilized gauze. This acts in a two-fold manner. First, it prevents any marked secondary hemorrhage, as sometimes occurs after the use of the suprarenal extract, and, secondly, it acts as a protection. It should, however, always be removed the day following. If the patient is not to be seen for a few days, under no condition should the canal be packed, but if much discharge is present, the patient should be directed to use the irrigation method for a few days, until the discharge diminishes sufficiently, or until the patient again comes under the observation of the surgeon for further treatment. In all cases where exuberant granulations or polypi have been removed from the auditory canal and middle ear, the subsequent treatment is carried out on exactly the same lines as that already mentioned, *i.e.*, keeping the parts sterile and clean, stimulating from time to time as needed, and later when the discharge diminishes, the use of the drops, before referred to, twice a day.

If, after an ear has been treated in this way for a period of ten days or two weeks, the discharge is still present, and there is a marked tendency to a reformation of the granulation tissue, then it may be said with a degree of certainty that we have to deal with dead bone farther back, and no time should be lost in its removal.

Aspergillus is quite frequently found just within the meatus, on the canal wall, on the remains of the drum membrane, or on the exposed internal tympanic wall where the ear has previously been the seat of a purulent inflammation and its presence may mislead us into thinking that the ear has begun to discharge again. The cause of this is the presence of this

fungus at one or more of the points just mentioned. It develops slowly in the beginning when it lodges upon the surface, owing to a lack of moisture, but later, when even a slight amount of moisture comes in contact with it, the growth is a rapid one, and the discharge given out from it is often offensive and accumulates around the meatus.

The treatment is simply keeping the parts clean by the ordinary method, and scrubbing the surface all over with a cotton-tipped probe dipped in the alcoholic solution, previously mentioned, and the insufflation of just enough finely powdered acetanilid or boric acid to cover the surface from which the fungus grows. A few treatments like this will suffice to clear up the condition as well as to relieve the excoriations caused by the discharge at the meatus.

In all cases of purulent disease of the middle ear, where, upon examination, we find the drainage insufficient we should lose no time in enlarging the opening through which the discharge is passing, and many times it is desirable, instead of enlarging the old perforation, to make a free incision through the drum membrane at some other point to facilitate more rapid drainage. This is particularly imperative when the discharge emanates from the lining membrane of the middle ear, and we find it being inadequately drained. It is in these cases that the subsequent use of the middle ear syringe is of the utmost value, as after a thorough cleansing of the tympanic cavity we can introduce the stimulating or astringent solutions, and a sufficient quantity should be used each time to completely fill the tympanic cavity. The fluid will often pass through and down into the Eustachian tube, but this will do no harm, provided the solutions used are not too strong, and rarely should we use a solution of silver here at first stronger than 1 per cent. If the case be a persistent one, this intratympanic syringing should be practised each day until the discharge is perceptibly lessened; then every second day, and later less frequently, as twice a week.

When a small amount of discharge continues despite all treatment and the parts upon inspection look indolent, the method suggested and practised by Blake, fitting a small sterilized piece of very thin paper over the opening existing, will often heal these perforations, if in no other way than by the mechanical irritation set up by their contact with the indolent surface. In applying these paper discs, after they are approximated closely to the drum membrane, they are gently pressed around their edges so as to adhere firmly. After they have been satisfactorily approximated, a small amount of powdered acetanilid or boric acid is dusted over their surface. Such a dressing will remain in place from two to eight days, and when the parts are again inspected we find the disc, though still adherent to the drum membrane, has gradually worked toward the edge of the drum, exposing a part or the whole of the perforation, while little or no moisture is present. A second disc, sterilized in the same manner, is now placed over the opening, leaving the primary one undisturbed, and partially overlapping it. Usually two or three such applications serve in a large number of cases to completely stop the discharge and close the opening. The protection given by the disc, no doubt, hastens the changes taking place in the pathological mucous surface of the middle ear.

To improve the hearing after we have cured the discharge is the next step in the treatment of this disease. When marked destruction of the tympanic membrane has taken place and the ossicles are bound down by adhesions, we usually get a marked diminution in the function of hearing, unless we later divide the adhesions existing, and this procedure can be quite easily carried out after the discharge has ceased, and will be followed in many cases by a decided improvement in audition. Some of the cases thus subsequently operated upon show no improvement, but the large majority do improve, and for this reason we should not fail to give this part of the treatment a fair trial. Personally I have seen only two cases out of a total of twenty-four that did not improve under this procedure.

It is usual in an ordinary case for the hearing to improve when the discharge ceases, and here as an aid to restoring the function of hearing we use the ordinary method of inflation and vaporization of the middle ear, as it prevents the excessive formation of adhesions, and when these adhesions have taken place, it tends to stretch them, as well as stretch and make more pliable that portion of the drum membrane still intact, and also exerts the same influence, to a greater or less degree, upon that part of the drum membrane which is forming anew.

This method of treatment should, if possible, be carried out three times a week at first, and, as improvement begins to take place, the frequency should be diminished, according to the indications present in each case. In many of these cases during their convalescence, and after the discharge has ceased, there will be complaint made of a most distressing tinnitus, and one which does not clear up even though the frequent inflations spoken of have been practised. Here the administration internally of small and gradually increasing doses of the potassium iodide will be followed by a marked relief in a large number of cases. Begin with five grains three times a day, gradually increasing the dose until the relief is secured. Usually when the patient has taken about ten grains three times a day for several days, this symptom will gradually diminish, and in a fair number of cases will disappear altogether. Its action no doubt is due to its stimulating properties, and this causes an

absorption of a small amount of exudate or recently formed deposit within the middle ear.

If any decided labyrinthine involvement is already present, then, of course, the severing of the adhesions above spoken of is contraindicated from the standpoint of any improvement.

In all cases in which upon our first examination we discover intratympanic caries existing, it is useless to attempt a cure of this condition except by an operation on the middle ear for the removal of this pathological condition, or when a case has been systematically and persistently treated over a period of from three to four weeks, with little or no improvement, a most careful examination with the probe should be made under cocaine anesthesia; usually we will find an area of carious bone as the cause of the continuance of the symptoms.

When caries is found we then have the choice of its removal through the canal, or by the opening of the mastoid process and doing a Swartz-Staacke operation. If the case be one in which there is no evidence of a mastoid involvement either past or present, it is much better to remove the caries through the canal and not subject the patient to the unpleasantness of a prolonged convalescence as well as an unsightly scar for the rest of his life. The caries can always be removed through the canal, care being taken not to injure the facial nerve, and the canal packed with plain sterilized gauze, removed each day for three or four days, and replaced; after this the ear will need to be irrigated only once or twice a day for a week or ten days, and in two weeks from the time of the operation we should have a case in which the discharge has ceased and one requiring only a slight amount of care and treatment to improve its functions.

Should there be any evidence of mastoid involvement at the time of operation, by no means should we operate through the canal, but by the posterior method.

Regarding the prognosis for hearing in these cases, we should never promise them that the hearing will be improved, but that it will be as good as before the operation, but clinical experience teaches us that a few do improve markedly, but they are usually in patients who are under twenty-five years of age.

In all cases coming under our observation for treatment, we should never lose sight of the fact that we are medical practitioners first and specialists second, and all cases, when indications demand it, should have general building up and tonic treatment in order that the local condition may improve the more rapidly. This will result if the patient receives a surplus of nutrition through the medium of the general system, and many cases which today are chronic, had they had the building-up process when first attacked by the local disease, would never have been prolonged into this less hopeful stage.

62 West Fifty-second Street.

TUBERCULOSIS OF THE IRIS.

BY WM. F. MITTENDORF, M.D.,
OF NEW YORK.

Tuberculous affections of the eye, especially of the iris, the ciliary body and the choroid have claimed the attention of the medical world much more of late than formerly. The true nature of affections of this kind has been known only for the last thirty years, and yet there are many interesting cases of this kind on record.

The close connection of diseases of this kind with pulmonary or general tuberculosis makes their early recognition a matter of supreme importance, and great credit is due to efforts of many European writers, such as Leber, Schieck, Langhans, Colnheim and others and to Dr. Chas. Bull of this country for their researches in regard to the true nature of these dangerous diseases of the eye.

Tuberculosis may affect, of course, nearly any part of the eyeball, yet the iris and the choroid are much more frequently invaded than any other part of this organ and affections of the former will claim our attention especially to-day. The starting point of the tuberculous iritis may be in the iris itself or in the ciliary body or the choroid, but very soon it spreads from the one to the other and the entire eyeball or at least its inner parts are apt to become involved. It is sometimes a primary, but usually a secondary affection and may be divided into two classes, the solitary and multiple form, and the latter may be divided again into an acute and chronic kind. This division is partly due to the number of tuberculous deposits to be found in the iris, partly to the clinical difference of the attacks and partly to its connection with tuberculous affections of other parts of the body.

As a rule, it is a disease of youth or early middle life and only one eye is affected in nearly every instance, in which respects it differs from tuberculous affections of the choroid, which as a rule, are of the miliary form and attack both eyes at the same time. The first class to be described comprises those cases which are usually connected, more or less directly, with tuberculous disease of the general system, not necessarily of the lungs however, but may be associated with tuberculous affections of the meninges, the peritoneum or the kidneys. The disease generally assumes a more or less acute form at once, as characterized by the formation of one or more grayish nodules developing in the iris tissue, consisting of inflammatory products with a small number of bacilli and is marked by the early appearance of ciliary injection and is accompanied by intense pain in the eye and forehead; many synechiæ form; the eyeball becomes

red and painful to the touch and the disease resembles in many respects an acute attack of rheumatic or specific iritis. But the tuberculous deposits, which were in the beginning like small, grayish bodies, soon become larger and more vascular and appear of a reddish-brown color. They are apt to coalesce and eventually break down, forming a large, soft, brownish mass projecting into the anterior chamber. The pain is often so intense that an enucleation of the eye may be called for on this account alone. The vision becomes impaired early and the pupil fills up with exudative matter, and firm adhesions of the iris to the lens form early in the course of the disease. The aqueous humor is cloudy and mixed with broken down tuberculous matter. If the disease is not interfered with the cornea may break down on account of contact with the tuberculous deposit and a large ulcerating surface with numerous blood-vessels in it is formed. These may give rise to hemorrhages and discharge considerably. The entire eyeball becomes filled with tuberculous matter and even the orbital tissues may become involved; on the other hand, a shrinking of the eyeball may take place after the perforation of the cornea. This form, therefore, even in milder cases results in great impairment or total loss of vision or in destruction of the entire eyeball, and not infrequently the death of the patient is brought about by similar simultaneous attacks of the meninges, or lungs, or by a direct extension of the disease to the brain.

Another form of tuberculous disease of the iris, which is not so violent in its onset, and in which there are probably not so many bacilli present in the deposits, occurs usually during the earlier stages of pulmonary tuberculosis. It is characterized by the appearance of multiple, generally more than one or two, tuberculous deposits in the iris. This form is accompanied by some pain and photophobia and more or less invasion of the pupillary border of the iris, which in turn leads to the formation of the posterior synechiæ.

This disease, which was first described by Leber, runs a much slower course than the first form. It may last for many months, and the iritis may be entirely relieved if the general condition of the patient improves, or it may result in occlusion of the pupil with eventual shrinking of the eyeball. These tuberculous deposits are usually isolated, yellowish in color and they rarely coalesce; they become vascular after some time and may remain in this shape for a long period. Sometimes absorption of the nodules appears to take place and, if the pupil remains well dilated during the course of the disease and is free of inflammatory deposit, the eye may retain a fair amount of vision. There is usually but little ciliary injection and not much change in the appearance of the eye during the course of the disease.

The third form is a more serious one and usually leads to great impairment of vision or loss of the eyeball. It manifests itself in the shape of a single tuberculous deposit, situated at the bottom of the anterior chamber, projecting into the aqueous humor, and involves the ciliary body frequently from the onset. It is very painful from the beginning and is associated with photophobia and lacrimation. Adhesions of the iris to the lens are most frequently found at the lower half of the pupillary border; later the pupil becomes narrow and is often occluded by exudation and this naturally results in great impairment of vision. The pupil may eventually yield to the action of strong solutions of atropine, but the lower half of it is usually firmly adherent to the lens. As the tumor develops it presses on the cornea, which in that case will soon break down. This will lead to the loss of the eye. The eye, as a rule, will have to be enucleated, but sometimes it may undergo a phthisical degeneration. However, even this form of the disease, which usually affects young people at the age of puberty, or during childhood, may sometimes yield to treatment, and partial recovery of the sight may be obtained.

It may seem strange that in all the cases which come under my observation the left eye was always the diseased one, but this seems to be the experience of other observers likewise; nor have I seen a single case in which the disease attacked both eyes at the same time, not even in the form of a sympathetic ophthalmia. Of course this does not refer to cases of miliary tuberculosis of the choroid, which as a rule attacks both eyes, usually at the same time.

The treatment of affections of this kind should be directed to the tuberculous condition of the system in the first place, and here the usual remedies, for instance, creosote in large doses or the use of Koch's tuberculin would recommend themselves to us. But on account of the iritis or iridocystitis, which is nearly always present, the most energetic treatment for this complication must be promptly resorted to and here the use of an atropine solution, four or six grains to the ounce of water, is of the greatest benefit, as it not only tends to relieve the intense pain and the photophobia, but also leads to a dilatation of the pupil and prevents the filling up of this space by exudation. This in turn helps to retain some vision to the eye during the attack and lessens the danger of great impairment of vision should the patient ultimately recover from the disease. Ice-compresses are not always grateful to the patient and as a rule hot water applications give more relief. Especially is this true when the cornea becomes involved during the course of the disease. Leeches to the temporal region are usually not indicated, because the patients are apt to be in poor health and cannot afford to lose any great amount of blood. Yet in acute or rapidly progressing cases, especially if associated with meningitis, the use of three or four leeches applied to the temporal region may relieve the intense pain and congestion of the eye. Even morphine may be given if the patient is in great pain and if very restless at night. On account of the

local use of rather strong solutions of atropine to the eye, of which more or less is absorbed, fairly large doses of morphine may be given with impunity, even to children.

In regard to operative treatment, an iridectomy, including the tuberculous deposit, may be thought of, if the latter is confined to only a small portion of the iris and the rest of the iris-tissue is in fairly healthy condition. But even under these favorable conditions the prognosis should be very guarded, as the disease may reappear shortly after the operation and lead to a rapid destruction of the eye. If there is any broken-down tissue present in the anterior chamber this should be carefully washed out at the time of the operation by means of a very mild solution of bichloride of mercury; but this fact, that the contents of the anterior chamber have become infected, should be a caution not to operate at all. It is therefore a safe rule that, if the tuberculous iritis does not show any signs of improvement after the usual internal and local remedies have been tried, and especially if the disease appears to be progressive in spite of them, the complete removal of the affected eye must be resorted to. Even if the enucleation of the eye does not always prevent an infection of other organs of the body, yet it may at times save the life of the patient by removing the principal cause of danger; even if other organs of the body are already affected and the chances of saving the life of the patient be very slight, the removal of an eye, blind from the effects of the tuberculous disease, may be called for, if the pain is very severe and robs the patient of sleep and strength.

I here present the histories of three cases which I have seen in succession in order to illustrate the three forms just described.

Case I.—Mary N., nineteen years of age, living on Staten Island, had a very sore left eye for which she was treated by a colleague, who had recognized the disease and had advised the removal of the affected eye. This procedure, however, was strenuously objected to by the entire family, including the patient. I saw the case a few weeks later. The patient had been obliged to go to bed and I found her in a greatly debilitated condition, with fever and indications of a beginning tuberculous meningitis and an invasion of the lungs, probably of a miliary type; the apices of both lungs being involved. The eye itself was intensely inflamed and she suffered the most agonizing pain day and night. Photophobia was very marked; she had to be kept in a very dark room. The cornea was a little hazy and in the iris tissue three moderately large deposits of light yellowish appearance, with some vascularity, were found; the pupil was irregularly dilated, and partly filled with exudation and there was no perception of light. This latter fact and the intense suffering of the patient made it desirable to remove the eye, which was done under ether. The patient felt greatly relieved after the removal of the eye, as the local attacks of pain had disappeared, but the meningitis ran its usual course and in a little more than a week the young girl died of tuberculous meningitis. The formations seen in the iris of the enucleated eye proved to be tuberculous deposits.

Case II.—A young man about twenty-three years of age. His eye became badly inflamed during a stay in the Berkshire Hills, where he had gone on account of an annoying and debilitating cough which had troubled him during the spring of 1899. The case was seen by an eminent specialist in the neighborhood and was later, on his return to the city during the latter part of the summer, referred to me. The left eye showed signs of an old inflammation and in the iris tissue four small, yellowish deposits could be seen. There was a mild form of iritis which had evidently existed for some time, for there were not only several synechiæ but also some small brown deposits on the anterior surface of the lens where former adhesions had been torn loose. The sight of this eye was fairly good $= {}^{20}/_{70}$; that of right, not implicated eye was about normal. The ciliary injection was not marked and the pain had never been very great. The patient denied all specific trouble of any kind and the disease had not been affected by large doses of iodide of potash. There was dulness of the apex of the right lung and I ordered creosote and cod-liver oil after the futility of the iodide treatment had been shown. The eye improved considerably shortly after this and the patient went back to the mountains. Two months later he returned on account of a slight relapse of iritis, but this improved after the usual local treatment had been instituted and his sight improved to ${}^{20}/_{40}$. The pulmonary trouble was not very bad and the patient was of a cheerful and hopeful disposition which was evidently greatly in his favor. He went out of town again and I have not seen him since. At the time of his last visit the tuberculous deposits of the iris were perhaps a little smaller and the iritis had subsided promptly after the usual treatment.

Case III.—The last case was that of a young Italian lad, about twelve years old, who had been treated at some of our dispensaries for several weeks on account of a badly inflamed left eye. The boy was rather pale and anemic and all the glands of his neck were very much enlarged. He suffered from intense pain and photophobia and the eye was very much injected, especially around the lower half of the cornea. This latter part of the eye was fairly clear, but the aqueous was a little hazy; the pupil was partly under the influence of atropine and the upper part of it was free and dilated, but the lower half was firmly adherent to the anterior capsule of the lens. The iris was somewhat discolored and from the bottom of the anterior chamber a small, narrow tumor projected upwards into the anterior chamber. It was yellowish brown in color and surrounded by some blood-vessels at its base and was perhaps two to three m.m. high and one to two m.m. broad.

The patient was brought to me because it had

been proposed at the hospital to remove the eye. After the energetic use of atropine, the pupil began to dilate even below, having only two firm adhesions which could not be torn, and on the anterior as well as on the posterior lower half of the lens an opacity was revealed which was evidently due to inflammatory deposits of the iris and ciliary body. The posterior opacity ran up almost as high as that on the anterior surface of the lens. As the upper part of the iris appeared fairly normal and the vision of the eye proved to be like $^{20}/_{200}$ after the full dilatation of the pupil, and as the interior of the eye was fairly clear and the optic disc, as far as could be seen, was apparently normal, I decided to resort to medical treatment before operating and ordered a strong solution of atropine locally and ten drops of creosote in cod-liver oil three times a day and a generous meat and milk diet. I did not see the patient for two weeks after this and by this time a great change for the better had taken place; the tuberculous deposit, for such I took it to be, had shrunk considerably, and the posterior synechiæ were very much thinner. After two more weeks there was hardly any trace of the growth visible, but the synechiæ and the deposit on the anterior and posterior lens-capsule were still present. There was no pain and no photophobia; the glands of the neck were less swollen and the general health of the child was very much better and he had discarded the dark glasses I had given him. Of course there is some doubt as to the true nature of the disease as long as no inoculations of the suspicious deposits on rabbit's eyes were made, but as idiopathic iritis in children is so extremely rare and as the mother of the last patient had died of phthisis and as the action of creosote appeared to be so very favorable, and as there were no signs of either acquired or congenital syphilis, and as there was no history of any injury or rheumatism, the tuberculous nature of the disease was more than probable, in spite of its favorable termination.

MEDICAL PROGRESS.

Biological Determination of Human Blood.—N. DIEUDONNÉ (*Münch. med Woch.*, Apr. 2, 1901) injected blood obtained from human placentæ, strongly albuminous urine and pleural exudate subcutaneously in gradually increasing doses into rabbits. Several days after the final injection, venesection was done and the serum tested with small quantities of blood from various sources. Only in the case of human blood a distinct, flocculent precipitate could be obtained. It differed little whether the serum was obtained from the rabbits treated with blood, urine or pleural exudate.

Perforation in Typhoid.—This accident may be divided into two stages, the perforation itself, and the consecutive peritonitis. A majority of the cases occur early in the third week. After citing three cases of laparatomy for perforation, with recovery in one case, death during operation in another, and in the third a healthy bowel wound but subsequent death from toxemia, WILLIAM OSLER (*Proc. Phila. Co. Med. Soc.*, Feb., 1901) throws out the time-honored picture of perforation, the Hippocratic facies, the feebly running pulse, the profuse sweat, distended, motionless abdomen, as that of peritonitis and an omen of death. That perforation may be recognized early enough for surgical aid, he directs the nurse to give notice of any complaint of abdominal pain, hiccough, vomiting, sweating, rise of pulse or respiration, or signs of collapse. The physician should note whether the pain is an aggravation of slight abdominal pain, or sudden, intense, and, though relieved by stupes and ordinary measures, recurring in paroxysms and growing worse; whether diffuse or localized, in hypogastric or right iliac region, and its radiation (as to penis in one case at Johns Hopkins). Abdominal pain of severe character may mean acute pleurisy, cholecystitis, distended bladder, packed rectum, or may follow an enema. Note whether abdomen is flat, scaphoid, or distended, and if the last, whether uniform or chiefly hypogastric. Are the respiratory movements present, uniform, and seen both below and above the navel? On palpation, note the tension, tenderness, locality and extent and degree of pressure necessary to elicit muscle rigidity and spasm, absence or presence especially in hypogastrium and right iliac fossa. On percussion note whether liver-flatness is diminished even in a flat abdomen. On auscultation listen for friction-sounds, or obliteration of peristaltic signs. Examine rectum for tenderness and for fulness between rectum and bladder, and note character and frequency of stools and presence of blood or sloughs. The facies may show a changed expression, slight or marked risus, pallor, sweating, etc.; the pulse may change in rhythm, rate, and force. Note whether temperature drops or not, whether respiration suddenly increases or becomes infrequent, whether shallow or sighing. The leucocytes should be counted every hour and are either stationary or rising. The red-cell count and hemoglobin will distingnish from hemorrhage. These points noted make the diagnosis possible in many cases, and then no time should be lost in giving the patient the benefit of operation. As typhoid patients bear operation well it is better to err in favor of surgery than to let valuable time be lost in waiting for further confirmatory evidence.

Fracture Bandages.—F. BAHR (*Centralbl. f. Chir.*, No. 12, 1901) considers the following little technic exceedingly valuable in preventing displacement of fragments within the plaster-of-Paris splints after reduction has once been made. While one assistant makes the extension and after the fragments are apposed, another assistant passes loops of rather wide bandage about the limb, one just above and a second just below the point of separation. Having taken the ends

of each loop in either hand he gently makes traction in opposite directions in the plane of greatest former displacement. This maneuver holds the bone-ends together while the plaster-of-Paris bandage is carefully applied. A window is necessarily made at the points where the slings above described emerge, which are later bridged by wooden splints over which the ends of the loops are tied, each on its own side maintaining the pull. In this manner all tendency toward recurrence of the deformity is checked. The procedure has one hazard, which is easily avoided if a little care is exercised, it is that of making the ties too tight over the soft parts. After an extended application of this plan he has never seen any such difficulty arise.

Ox-Serum in Rectal Feeding.—O. Grunbaum (*British Med. Jour.*, Apr. 6, 1901) outlines some of the advantages to be obtained from this form of alimentation. His observations have been on women, gastric ulcer being present in a number of the cases. Starting with the proviso that the patient must have the equivalent of about 2,000 calories, he has proceeded by a very careful series of observations to show that from ox-serum in minimum doses she absorbs the maximum nourishment. She requires about 85 grains of proteid, 40 of fat and 320 of carbohydrate. To the serum he adds glucose and milk, with liquor pancreaticus. Some of the advantages of the serum are its constant amount of proteid, its small cost, the ease of its preparation and the odorless character of the stools. His formula, given every four hours, is as follows: Serum, 90 c.c.; milk, 60 c.c.; glucose, 15 gm.; liquor pancreaticus, q. s. By giving a cleansing enema just prior to each injection, he has been able to note the relative rates of absorption. Fat is not taken up kindly by the colonic and rectal mucous membrane; starches or glucose are readily assimilated and, if not stronger than 15 per cent., are well retained and do not irritate. The heat of this diet is 578 calories. He increases it 300 calories by the subcutaneous injection of sterilized olive oil, from 30-40 c.c. being given daily. By these methods he finds the loss in weight can be reduced to 750 grains a week.

Arteriosclerosis and the Heart.—The cause of arteriosclerosis in young or middle-aged people may be due to the influence of heredity so that the arteries prematurely show their tendency to degenerate. B. Robinson (*N. Y. Med. Jour.*, Apr. 27, 1901) further believes that it is not necessary to find alcoholism, gout, lead or syphilis, as a causative factor, but continuous overwork, poor assimilation of food and irregular habits of life may also be determining factors. Renal disease may be only secondary, but is frequently, no doubt, a direct cause. It is in this diffuse form among middle-aged vigorous men that we find the greatest degrees of cardiac hypertrophy. Senile changes rarely cause hypertrophy of any degree. The essential change is in the small arteries where a thickening occurs due to the hyaline degeneration of the muscular layer. In mitral stenosis a sclerotic condition of the pulmonary veins is not uncommon. High tension may exist without sclerosis, but it is then variable. When it exists in a continuous persistent manner it is usually due to sclerosis. While heart stimulants, as strychnine, strophanthus and digitalis, are often indicated, potassium iodide in moderate doses for long periods is the most useful drug and should be prescribed with occasional interruptions.

Tobacco and Glycosuria.—Very little is said in works upon diabetes about the causative relation which tobacco holds to glycosuria. H. Stern (*Med. Rec.*, Apr. 27, 1901) has reported four cases in which this influence was carefully watched. By experimentation it was found that the use of from five to ten cigars during the day would increase the glycosuria at least from one to two per cent. In one case in which a percentage of 1.35 continued under an antidiabetic diet, the cessation of the free use of tobacco resulted in a permanent disappearance of glucose from the urine. Nicotine is not believed to be the offending agent for nearly all of it is decomposed by heat. As the empyreumatic compounds and acrid substances have their chief influence upon the mucous membrane their importance in this connection is also considered slight. Carbonic oxide gas is here thought to be the most poisonous matter contained in tobacco smoke and largely responsible for the melliturla. The amount of CO evolved is not only dependent upon the quality of the tobacco, upon its moisture and combustibility, but also upon the mode of manufacture and consistency. Pipes do not seem to be so injurious for oxidation is here more free. In non-lethal CO poisoning the glycosuria lasts only a few days and the sugar excreted does not usually amount to more than 1.5 per cent. When resulting from the use of cigars the glycosuria persists as long as the causative factor continues.

Extreme Simple Anemia.—A very marked case of simple anemia is reported by R. Floyd and W. J. Gies (*Med. Rec.*, Apr. 27, 1901) in which the blood showed upon the first examination: Hemoglobin, 12 per cent.; red cells, 750,000; white cells, 3,300. The principal symptoms were dyspnea, with attacks of palpitation, vomiting, diarrhea and sometimes edema. She was started on sulphate of iron, gr. xxiv, and arsenious acid, gr. $^1/_{10}$, in twenty-four hours. Her symptoms very rapidly disappeared and at the end of the fourth week the hemoglobin was 45 per cent.; red cells, 1,568,000; and white cells 5,600. The variation in size and shape which was so noticeable at first had almost entirely disappeared. At the end of the ninth week, hemoglobin, 97 per cent.; red cells, 3,796,000; white cells, 7,000. The ferrous sulphate was increased to grs. xxxix during the latter part of the illness and seemed to be very well borne. Another case which proved to be pernicious anemia is compared with the above. The analysis of the

blood showed hemoglobin, 22 per cent.; red cells, 756,000; white cells, 4,800. Only one normoblast was found and the poikilocytosis was not more marked than in the first case. In spite of energetic treatment she died within one week. The analyses of the blood in these two cases were very similar and from these alone diagnosis would have been impossible. The clinical features which were significant were, the age of the first, nineteen; of the second, sixty-four; no cachectic color in the first, marked in the second; a rapid response to treatment in the first, no response in the last.

Treatment of Penumonia in Children.—It is believed by L. Fischer (*N. Y. Med. Jour.*, Apr. 27, 1901) that pneumonia may sometimes be aborted by the use of one-drop doses of aconite repeated every hour for six doses, with spiritus mindereri hourly until diaphoresis occurs. Calomel should be given in small, frequently repeated doses till liquid stools are passed. Water should be given freely for the diaphoretic and diuretic effect. Antipyretics should seldom, if ever, be used. The cold tub or pack is especially valuable and for stimulation to the skin and heart the cold tub may be advantageously alternated with a warm bath. Vigorous rubbing should be kept up. Oxygen should be freely given in the form of fresh air and, if drafts are prevented, it is much better to have the windows opened. To relieve a hacking cough and give sleep, codeine in doses of one-tenth of a grain may be used if necessary, but should not be repeated often. Feeding is an essential element in the treatment, especially in the prolonged bronchopneumonia cases and the addition of a small amount of whisky is thought to be of assistance.

Bovine and Human Tuberculosis.—Having noted the excess of virulence of the bacilli of bovine tuberculosis over those of human origin, R. R. Dinwiddie (*Bulletin 63, Arkansas Agricultural Experiment Station*) performed experiments with the following results: Cultures from human sputum caused in pigs a chronic tuberculosis with emaciation. Cattle proved very resistant and in no case was a progressive or even permanent infection obtained. Sheep were more susceptible than cows as evidenced by persistence of the tuberculin reaction and larger local lesions, but suffered no impairment of general health. Toward cultures of bovine origin all three species proved highly susceptible. The writer concludes that stabling, as it causes the breathing of vitiated air, may account for the increased susceptibility of these animals to the naturally-acquired disease, over their susceptibility to inoculation.

THERAPEUTIC HINTS.

Diabetes Mellitus.—If sugar continues in the urine even in abstinence from all carbohydrate food, including milk, says George Dock (*Physician and Surgeon*, Mch., 1901) the case is severe and the food must be increased to prevent inanition. Some starchy article, such as bread or potato, may be added in small quantity, gradually increased. If there is a large amount of sugar, carbohydrates must not be cut off suddenly, but gradually for two or three days; if the sugar is small in amount the carbohydrates may be stopped at once. Then gradually ascertain the tolerance for bread, potatoes, other vegetables, sugar, beer, etc., so that the dietary may be made as wide as possible. Milk (not skim milk), fat in all forms (as cream, bacon, oil, butter). Cheese, etc., can be used with great advantage. When there are evidences of intoxication foreboding the dreaded coma, give at once large doses of alkalies, as much as 13 grams (200 grains) daily. Small doses meet with failure. Some should be given intravenously as well as by mouth.

Syphilis.—Verrier reports the use of the serum of Jeltschinsky of Moscow, which is not of the nature of an antisyphilitic serum, but which seems to modify and stop the inroads of syphilis. He has met with much success in fifteen cases, one of them a case of pregnancy, with both father and mother seriously infected, and in which under these inoculations a non-syphilitic child was born.—*Le Progrès Médical*, Mch. 23, 1901.

Hyperemesis of Pregnancy.—J. W. McLane advises complete rest, in bed, have all food given by the nurse, and keep patient's mind away from the stomach. Matzoon, c.c. 4.0-8.0 (3i-ij) is easiest borne, then gradually add peptonized milk, beef tea, preferably unsalted, eggs, and raw oysters. An enema containing tincture of opium a few drops, and brandy 4 c.c. (3i) is good. Examine the uterus and if anteverted or retroverted or bound with adhesions, tampon with boric-acid vaseline or glycerin gauze. If the vomiting cannot be stopped anesthetize, scoop out ovum with the finger, curette, douche, and insert a gauze drain.

Intertrigo.—The opposing surfaces must be separated by lint, the furrows kept clean, and all freely dusted with starch, talc, lycopodium or other powder. Zinc oxide, boric acid, or other astringents may be added, especially compound stearate of zinc. As a rule, powders are better than ointments. Lassar's paste or lotions such as calamine lotion, or saturated solution of boric acid may be used.

Hardaway recommends:

℞ Thymol. .....gm. 0.06 (gr. i)
Pulv. zinci oleat. 30.0 (3i)

In infants the treatment is that of eczema. The breast-milk or other milk must be investigated, and water must be kept from the skin. In male children a tight prepuce may cause dribbling of the urine with constantly wet diapers. Cod-liver oil is often a good internal remedy.—*G. T. Jackson in "Diseases of the Skin."*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MAY 25, 1901.

THE REORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

For a number of years past it has been becoming very apparent that the American Medical Association under its present Constitution and By-laws is an extremely ill-knit and unwieldy body. The crudity of its early construction is now too manifest and the recent steps of the committee of reorganization are deserving of special consideration.

The two greatest integral faults with the early plan of organization have been the method of delegate representation and the lack of a coherent scheme of allied associations in the several States. The number of delegates has been too many, business affairs, medical politics and medical legislation have been in large part ineffectual, because of the unwieldly character of this body and the heterogeneous character of the affiliated societies has prevented anything like a comprehensive and coordinate association with a unity of ideas and purposes.

To obviate the confusion caused by the number of delegates the Committee proposes the establishment of a House of Delegates. This body is to undertake the business of the Association and is to consist of members from the State Association, the apportionment being one member in the House for 500 in the State Association. Inasmuch as there is thus far no regularity concerning State associations the committee outlines a plan of organization by which the county associations become the integral parts of the State Association without any increase of dues.

We cordially endorse the report of this committee and believe that a way is offered by which the A. M. A. may be made a more representative body which shall deserve the respect of the entire medical profession. By the general terms of the report many of the objectionable elements, especially those relative to the politics of the organization, will be eliminated and we second the hope of the Committee of Organization that "If the Association will give its sanction to these recommendations, there will be good reason to hope that in five years the profession throughout the entire country may be welded into a compact organism, whose power to influence public sentiment will be almost unlimited, and whose requests for desirable legislation will everywhere be met with that respect which the politician always has for organized votes. With the Association in constant, personal, definite, and essential touch with each State medical society, and through them with the societies in every county, the profession of medicine can at no distant day demand and receive that respect from lawmakers, from government officials, and from the general public to which it is admittedly entitled by reason of its ideals, its education, and its power for doing good to all mankind."

LIFE INSURANCE AND CHRISTIAN SCIENCE.

At the instance of a correspondent the MEDICAL NEWS wrote to all of the regular old line life insurance companies, asking what steps, if any, had been taken with reference to the acceptance of risks of individuals who professed to believe in the unadulterated doctrine of Christian Science. Further what was going to be their attitude toward the claims of those dying in the faith. With but few exceptions the companies have maintained a discreet silence.

While we may not be interested in what happens to the individual who pins his faith to the doctrine of the non-existence of disease and pays the penalty which nature metes out with relentless irony to all those who ignore

the general laws of experience, it is important that the insuring public and more particularly, from our own point of view at least, the physician, should know in what manner the Life Insurance Companies intend to protect his interests by a careful scrutiny of its risks. Bad risks, if accepted by such companies, mean diminished returns on an insurance investment and since the protection of its policy holders is the foundation of any company's success some expression of opinion on this point is their duty.

It is therefore a sign of awakening on the part of insurers to the importance of the situation that a mutual benefit association in New Jersey has taken radical steps to protect its more enlightened members.

"In denying insurance to the dangerous fanatics of whom the 'Christian Scientists' are the best known variety," says the *Times*, "the New Jersey Grand Council of the Royal Arcanum has taken a stand that is open to criticism only because it was not taken long ago. Every other organization of the same character ought instantly to imitate the example thus set, and delay in doing so simply subjects to unjustifiable risk the property rights of the sane members of the societies. 'All persons,' to use the words of the resolution adopted by the Grand Council in explanation of its course, 'who reject, refuse, or neglect the aid of medical science are a very dangerous risk from an insurance standpoint.' That is an unquestionable truth, clearly stated. Since the 'Christian Scientists' deny the existence of disease and of death itself, the commonest sort of consistency demands that they voluntarily get out of the mutual insurance organizations, allow their policies in the regular insurance companies to lapse, and carefully refrain from stultifying themselves by taking out any new policies. If they will not do this—and of course they won't, as consistency is something they know nothing about—compulsion should be applied exactly as the Royal Arcanum has applied it. A little discipline of the same sort, used in this and other directions where it is needed, would tend to bring back to their senses all the believers in 'faith cure' except those whose insanity is irremediable, and there are not many so far gone as that. The follower of any one of these delusions is not a safe person with whom to have either business or social relations. The means of applying pressure are numerous, and as soon as sensible people begin to utilize them 'Christian Science' and all the allied or identical humbugs will be dissipated as rapidly as are other filth-laden miasms by the attack of good fresh breezes."

We feel that we can add little to the expressions here quoted but we would like to compel the regular insurance companies to enunciate the stand that they have decided to take in this matter. A concerted inquiry from physicians and particularly those contemplating the purchase of new policies would undoubtedly bring about an expression on their part as to how they are going to protect our interests.

PANCREATITIS: ITS ETIOLOGY; SYMPTOMS; TREATMENT.

The paper of Mr. A. W. Mayo-Robson of Leeds, England, merited all the wealth of applause it won the author at the recent meeting of the American Surgical Association in Baltimore. Outlining, as it did with the utmost clearness, the pioneer work of this great surgeon on an organ which is virtually the last of the abdominal viscera to surrender its virginity, so to speak, to the exploring knife, it marks the crest of the last great wave of surgical progress in this region.

Mr. Robson considers two factors as of ultra importance in the etiology of pancreatitis. The first, and by far the weightiest, is infection ascending by way of the duct, the second depends for its import on the excessively delicate network which holds the gland together. This is infinitely frailer than the corresponding stroma of the parotid, and, albeit the pancreas is so deeply and so centrally placed, there can be little doubt that abdominal blows of the very mildest character often wound the organ sufficiently to create the gravest kind of inflammations.

As yet, there are no pathognomonic symptoms of pancreatitis. Clinically, in the absence of tuberculous infection the most constant although by no means an invariable sign is the well-known extraordinary loss of weight. This takes place, in the classic cases, with appalling rapidity. Glycosuria and lipuria are occasionally present, although sugar does not appear early enough to have any diagnostic value, and, apparently, but very slight traces of the fat which accumulates in the body because of disordered pancreatic action are voided in the urine. The more natural channel for this unassimilable fat is the bowel, and clay-colored stools are far more significant of pan-

creatic than of choledochic involvement. The so-called "fat necrosis," a very general fatty change of macroscopic character which often invades organs as far distant from the pancreas as the heart and which was formerly considered pathognomonic of pancreatitis, has been shown to occur frequently, and to the same degree, in other diseases.

But if still in the dark so far as the clinical signs go, it seems very probable that ere long the results of pathological chemical study will afford means of an early and certain diagnosis of pancreatitis. When the urine of these cases is treated with phenyl-hydrazin, apparently so far without exception an abundance of singularly grouped rosetted yellow crystals is obtained. Mr. Mayo-Robson does not yet know their composition but he has found their presence of great value in establishing a differential diagnosis between simple catarrhal jaundice and icteroid pancreatitis.

Whatever may be the status of our ignorance in diagnosing pancreatitis, there is now no longer any question as to the treatment. It is both medical and surgical. Contrary to the too usual state of affairs, we know what to give, how much to give and why to give, calcium chloride. The degenerating fat in the body splits into glycerine and fatty acids—these acids unite with the calcium of the blood, which destroys, or limits, its power of coagulating. Hence calcium chloride in heroic doses is indicated especially in the hemorrhagic form. This term Mr. Mayo-Robson feels has been used too promiscuously. Inflammatory conditions of the pancreas are to be classified like those of any other organ, into chronic, sub-acute and acute. The hemorrhagic form is now to be considered a variety of the acute. The surgical treatment is immediate operation with the establishment of drainage. The position and direction of this varies with the chronicity or activity of the case. If it is of long standing, it is best accomplished indirectly by way of the marsupialized gall bladder; if acute it is through a retro-abdominal incision leading to the fat of the left perinephric region.

THE SUPPORT OF HOSPITALS.

The problem of how to pay the running expenses of a hospital confronts even the wealthiest institutions in the city. Legacies, gifts and endowments are pouring in, but only the interest goes to current expenses, and as the scale in which these expenses increase is simply enormous, in spite of careful management, in spite of balls, concerts, fairs, bequests and annual dues of members a deficit of from $10,000 to $70,000 may reasonably be looked for each year in the treasurer's report.

Inquiry at the offices of four of the largest hospitals in New York the other day, namely St. Luke's, Presbyterian, the German and the Roosevelt Hospital brings out the fact that the deficit in the Presbyterian was $77,364.32, St. Luke's $62,043, while the German and Roosevelt each were about $11,000 behind. Certainly the private patients pay well for their care, and it is not to be expected that the poor can give more for their nursing than they do, and yet it looks as though every patient were practically the recipient of the charity of the trustees who annually put their hands in their pockets and make up the deficit.

Viewed from the standpoint of strict economy, there is no valid excuse for marble halls, swarms of servants, silver service and the luxury of perfected details. But viewed from the standpoint of science, the hospitals that are training the best physicians and nurses that the city can supply, are doing something more than caring for the individual sick man. They are combatting the disease of a nation; and the few thousands given as charity are the best investment for the city's present and future health that can be made. In these days of luxuriously appointed steam yachts, enormous country houses, and elaborate entertainments it would be niggardly to deny to science and philanthropy any detail of perfection in the matter of plumbing, lighting, heating, apparatus, service and food, that the wealthy insist on having for their own comfort.

ECHOES AND NEWS.

NEW YORK.

New Building for the L. I. College Hospital.—A new building to replace the main structure of the Long Island College Hospital in Brooklyn, which was put up fifty years ago, is soon to be erected at a cost of over $175,000, of which about $120,000 has already been contributed. Henry W. Maxwell, it is said, subscribed $50,000. George Foster Peabody and Edward M. Shepard are also large contributors to the building fund.

Gifts of New York Hospital.—All the anatomical and pathological collections of the New York Hospital Museum have been given by the Governors of the hospital to the medical colleges of this city, the Post-Graduate Med-

ical College, the New York and Bellevue Hospital Medical College, the Cornell University Medical College, and the College of Physicians and Surgeons. These institutions arranged among themselves for the division of the collections donated. It was thought that as no lectures were given at the New York Hospital, and the museum was maintained only for exhibition to visiting doctors and others interested, the specimens could be used to better advantage in connection with the work of educational institutions.

Orthopedic Hospital Opens.—The New York State Hospital for the Care of Crippled and Deformed Children, which is situated in a remodeled house on a large tract of land on Paulding avenue near Tarrytown, on the Hudson River, was formally opened May 17th. The exercises consisted of addresses by Bishop Potter, who is President of the Board of Managers; Dr. Robert F. Weir of Columbia University, Prof. A. Alexander Smith of New York University, Prof. William M. Polk of Cornell University and William Rhinelander Stewart, President of the State Board of Charities. Bishop Potter in his opening address paid a high compliment to the work of Dr. Newton M. Shaffer, who was instrumental in getting the hospital ready to hand over unencumbered to the State. Dr. Weir said that this was the second hospital of its kind in the country. The first country to establish such a hospital at its expense, he said, was Russia. Dr. Weir explained that it was necessary to have such institutions in rural districts where the tendency to tuberculosis could be checked. The hospital has at present room for only about twenty-five or thirty patients, and eighteen are already there. Only children between four and sixteen years old who show some signs of being capable of improvement or ultimate recovery will be admitted. The Board of Managers consists of Bishop Potter, J. Hampden Robb, J. Adriance Bush, George Blagden, Jr., and Dr. Newton M. Shaffer. Dr. Shaffer will have the actual management. The consulting medical staff is composed of the professors of medicine and surgery of Cornell, the College of Physicians and Surgeons, the University-Bellevue Medical College, the medical department of the University of Buffalo, the Albany Medical College and the Long Island Medical College.

New Yorkers at the A. M. A. Meeting.—It is expected that Greater New York will be represented by more than two hundred physicians, at the annual meeting of the American Medical Association, to be held in St. Paul, Minn., June 4th to 7th. About half of these will take the special train which the New York State Medical Association has secured for the trip. This train will leave New York at 8.45 P.M., Saturday, June 1st, and stopping at various points along the line of the West Shore Railroad to pick up other members of the State Association, will reach St. Paul at 6.15 P.M. Monday. For those who will not go by this train, the New York Central offers an especially attractive table of fast through trains, and an excursion rate of one fare going and one-third fare returning, with stop-over privileges. From Chicago, the Northwestern road will run a special train of Pullman sleeping and buffet cars. This will leave Chicago at 7.30 P.M., arriving in St. Paul early Tuesday morning. The fare will be $13.50 for the round trip. This road also runs through expresses leaving Chicago at 9 A.M., 6.30, 10.00 and 10.15 P.M., on which reduced fare will be allowed. A considerable number of eastern physicians will leave to-day or early next week for the West, in order to attend meetings that precede that of the American Medical Association. New York members of the American Gynecological Society, which meets in Chicago May 28th to 30th, will go out on a special car, and will go to St. Paul next week to attend in that city the meetings of the American Association of Military Surgeons, May 29th to 31st, and of the American Academy of Medicine, June 1st and 3d. Nearly all of the New York and New England physicians, and many from other parts of the country, plan to make a brief sojourn at the Pan-American Exhibition at Buffalo a feature of the return trip.

PHILADELPHIA.

Jefferson Alumni.—The annual meeting and banquet of Jefferson Medical College Alumni Association was held May 14th at the Hotel Walton. The following officers were elected: President, Dr. W. W. Hartzell, Allentown; Corresponding Secretary, Dr. Henry Tucker, Philadelphia; Recording Secretary, Dr. Frank C. Hammond, Philadelphia; Treasurer, Dr. William Sweet, Philadelphia.

Diphtheria Not Quarantinable. — The steamer "Rhynland," which arrived at this port May 12th with three cases of diphtheria on board, was passed by both Federal and State quarantines. A list of the passengers who were to stop in Philadelphia, was furnished the Board of Health and the three persons afflicted were removed to the municipal hospital.

New Laboratories of the University.—The new medical laboratories of the University of Pennsylvania are to be unexcelled in arrangement and equipment. The building will be two stories in height above a high basement, and 200 by 340 feet in size. The first floor is to contain laboratories devoted to physiology and pharmacodynamics. The second floor will be devoted exclusively to pathology, including among others, laboratories for instruction in comparative, neurological, and surgical pathology. This building is but one of the group contemplated by the trustees, others being a new medical hall and an anatomical building.

Hatfield Prize Awarded.—The Nathan Lewis Hatfield prize of $500 has been awarded to Dr. H. F. Harris of Atlanta, Ga. The prize is awarded by the College of Physicians for a paper embodying the results of original research in medicine. The report of Dr. Harris was upon "A Study of the Alterations Produced in the Large Intestine of Dogs by the Amœba Coli, by Heat, and by Various Chemical Substances, with Notes on the Anatomy and Histology of the Viscus."

Hydrotherapeutic Institute.—At the discussion of Dr. Baruch's paper on Hydrotherapy at the last meeting of the County Medical Society, Dr. S. Solis-Cohen stated that every medical center, if not every city, should have an institute for the application of remedial agents other than drugs. These would include water, air, electricity, massage, etc. As a result it is said that a movement is under way to establish such an institute in this city.

Should Hospital Internes Give Anesthetics?—A discussion on this topic took place at a recent meeting of the Section on Gynecology of the College of Physicians, when Dr. C. H. Judd reported his conclusions and results in 850 cases of etherization. Dr. J. M. Baldy said that every institution should have a paid etherizer, the internes not being allowed to give anesthetics. He believes that the etherizer requires skill and training as well as the operator. New etherizers can be trained to replace retired ones by observing and helping the paid etherizer. A few minutes longer under ether because of an inexperienced etherizer may mean the death of a patient. The majority of cases of pneumonia following operation are due to faulty etherization. When the history is traced it will be found that the most of these patients have been black in the face or giving trouble at some time during the anesthetizing. The etherizer should never put his finger in the eye of a patient to test the reflexes. The supposed necessity of grasping the tongue by forceps is in nearly every instance due to faulty etherization. Dr. John C. Da Costa said that it was desirable to have a regular etherizer but he had seen some unfortunate results in the hands of so-called experts. His experience is that generally better results are obtained by trained hospital residents.

Dr. Thomas S. Kirkbride.—The exercises in commemoration of the one hundred and fiftieth anniversary of the Pennsylvania Hospital ended May 18th with an inspection of the insane department of the hospital. This brought to mind the splendid record of Dr. Thomas S. Kirkbride, the first superintendent, and from whom the institution took its still familiar term of "Kirkbride's Asylum." In his commemorative address Mr. Garrett paid a high tribute to the memory of Dr. Kirkbride. He was but twenty-two years of age when called to the superintendency of the new institution. To him more than to any other man of his time in this city was due the credit for the amelioration of the treatment of the insane. When the Pennsylvania Hospital was first opened it had two patients, and one of them was a lunatic. Large numbers followed and were restrained by harsh means according to the custom at that time. Dr. Kirkbride declared that corporal coercion and mechanical confinement should be done away with, and that life should be made attractive by amusements or cheerful tasks. He had a peculiar control over insane people, quieting otherwise uncontrollable maniacs. During the forty-two years of Dr. Kirkbride's service as head of the hospital it was the institution especially studied by foreign as well as American alienists.

Philadelphia and Appendicitis.—Dr. Oliver Wendell Holmes uttered his witticism about the novelist never hitting below the belt before the days of appendicitis. This malady has become a distinctly gentlemanly disease proper to discuss in polite society and we are not at all sure but New York will feel a little aggrieved at not being mentioned in the following excerpt from the New York *Sun* "Philadelphia has a new distinction, which will make her haughtier than ever. That city is the center and capital of appendicitis. According to Dr. Joseph Price, who read a paper on the subject to the County Medical Society last week, 'Philadelphia apparently lies in the center of a belt wherein appendicitis has been more common than in any other particular neighborhood in the United States.' The appendicitis belt takes in not only Philadelphia but the suburban towns near it, where most of the rich Philadelphians live. 'In this zone the number of cases of appendicitis is twice as large each year as that of any other locality of like character fortunately the rate of mortality is low. The rich Philadelphians can afford to have appendicitis and they do have it. But they seldom commit the indiscretion of dying of it. They take their pains as they take their pleasures, moderately and mildly. Physical geography accounts in part for the appendicitis belt. Much of the land is wet or very low, a country of miasma and malaria, of hay fever and grip; of grip, which is acknowledged to be an advance agent of appendicitis. Dr. Price says that a few years ago appendicitis was comparatively uncommon among women. The ratio was sixteen cases to three among women. Now women are about as liable to have the disease as men are. This increased susceptibility is attributed to the growth of outdoor physical exercise for women. Golf, cricket, bicycling, all forms of outdoor sport that are practised for long hours and in bad weather are resented by the appendix. O, well, if this be true, the appendix is even more of an ass than has been believed. People are not going to give up athletic exercise for the sake of

conciliating a notoriously useless and troublesome organ. A little appendicitis is not too high a price to pay for a good deal of sport. Besides, appendicitis in the appendicitis belt is gentle; and who can better bear the excision of the appendix than the strong and hearty folks who live out of doors?"

CHICAGO.

Chicago Sanitarium.—It is said that this city is to have a large private hotel and sanitarium where the wealthy patients of four of the leading physicians and surgeons can be treated and accommodated. The site has been secured, plans have been drawn, and a building permit will be asked for within a short time. The Chicago practitioners who form the sanitarium interest are said to be Drs. Frank Billings, Nicholas Senn, John B. Murphy, and Franklin H. Martin. The site secured is at the northwest corner of Eldridge Court and Michigan Avenue. The building will cost $400,000. It is to be eight stories high, stone front, and is to be equipped with the most modern conveniences.

Visiting Nurse Association.—This Association during April cared for 828 patients, and 3,573 visits were made by the fifteen staff members, according to a report issued a day or two ago.

Alexian Brothers' Hospital.—A testimonial concert was given for the benefit of this institution May 15th. This was the first of a series of annual entertainments which will be given for this purpose. The grounds and buildings for the new hospital cost $500,000, of which $400,000 has been paid, leaving an existing debt of $100,000. The proceeds of this concert amounted to $6,000.

Operation for Uterine Prolapse.—At a recent meeting of the Chicago Medical Society, Dr. J. Clarence Webster presented cases of post-menopausal complete prolapse of the uterus in which the prolapsed portion formed a swelling as large as two fists, hanging outside the vulva. In one case there was a papilloma about the size of a large walnut growing from the posterior lip of the cervix. He showed a photograph of one of the cases. It turned out fortunately that the papilloma was of a simple nature, therefore it did not come under consideration in these cases because the operative procedure carried out in each instance had reference to the prolapse, not to the tumor. In considering such a condition as post-menopausal prolapse of this grade, he dismissed from consideration all the simpler measures. Total extirpation of the uterus has been done by a number of operators, but has not been very favorably commented on for complete prolapse in old women. There have been failures after that operation. In these cases he adopted a special procedure which he thinks will be successful. In the first place, he performed extirpation of the uterus, which was considerably hypertrophied, for the purpose of drawing down the broad ligaments as far as possible and fastening them into the fornix of the vagina after the organ has been removed, in order that he might get upward traction of the broad ligaments at the end of the operative procedure. Extirpation is quite simple in such a case, and it is easy to draw down the broad ligaments and fasten them into the fornix of the vagina in the manner represented in a cast which was shown. That being done, he carried out extensive repair work, doing an anterior colporrhaphy, an oval flap being removed from the anterior wall. Again, in the same case an extensive colpo-perineorrhaphy was carried out posteriorly to diminish the vagina as much as possible in its diameter, and to build up a new sacral segment of the pelvic floor by a procedure which is slightly different from any method in use at the present time. The suture material used in every instance of this kind was formalin catgut buried, and superficial chromic catgut in the vaginal surfaces. The results have been very satisfactory in these patients, and they are nearly ready to leave the hospital.

GENERAL.

Harvard Medical College.—Plans for the new Medical School buildings have been completed, and a site has been chosen in the lot of twenty-six acres in Brookline which was purchased for the university last summer. According to these proposals, the school will be made up of three buildings facing an oblong court. Each of the buildings along the sides will be a series of wings connected by corridors, and each wing will be devoted to some special department. On the southeastern side the four wings are devoted respectively to anatomy, histology and embryology, hygiene, and pharmacology. The wings on the northwestern side are devoted to physiology, physiological chemistry, surgery, and bacteriology and pathology. The building on the side between these two sides will be given up to the administrative department of the Medical School. It is thought that these plans will require the expenditure of $2,000,000. Part of this sum can be realized by the sale of the present site, but as yet no other funds are forthcoming, and the beginning of the work will necessarily be delayed. The removal of the medical schools to the new site will probably not be completed for several years yet.

Obituary.—Dr. John A. Wells of Englewood, N. J., died on Monday, May 20th. He was about forty-five years of age and a leading physician in his locality.

Dr. William D. Thomas of the Chair of Psychology of Richmond (Va.) College died in Baltimore yesterday from a stroke of apoplexy. He went there a month ago to undergo

a surgical operation, which, apparently, was successful. Dr. Thomas had long been identified with the advanced education of the South.

Medical Society of City Hospital Alumni.—At the last meeting of the Medical Society of the (St. Louis) City Hospital Alumni held Thursday, May 16th, the following papers were read. Dr. A. H. Meisenbach—Surgical Operations on the Aged, with Report of Illustrative Cases; Dr. F. L. Reder—Vesico-vaginal Fistula—Operation according to Technic of Freund—Report of a Case; Dr. R. B. H. Gradwohl—The Use of the Double-knife in Histo-Pathology, with Demonstration.

Gastro-Enterological Association.—The following officers were elected at the annual meeting held in Washington, D. C., May 1st, 1901: President, John C. Hemmeter, M.D., Baltimore; 1st Vice-President, W. D. Booker, M.D., Baltimore; 2nd Vice-president, S. J. Meltzer, M.D., New York; Secretary and Treasurer, Charles D. Aaron, M.D., Detroit; Council, Max Einhorn, M.D., New York; D. D. Stewart, M.D., Philadelphia; A. L. Benedict, M.D., Buffalo. The next annual meeting of the "American Gastro-Enterological Association" will be held in Washington, D. C., May 2, 1902.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, May 11, 1901.

THE ROYAL SOCIETY—ELECTION OF MAJOR RONALD ROSS—MALARIA RESEARCHES AND RESEARCHERS—PATRICK MANSON AND HIS WORK—THE LONDON AND THE LIVERPOOL SCHOOLS OF TROPICAL MEDICINE—A "GIGANTIC" EXPERIMENT ON THE PREVENTION OF MALARIA—A KNIGHTHOOD FOR FREDERICK TREVES—MEDICAL APPOINTMENTS AT COURT—THE KING AND THE BRITISH MEDICAL ASSOCIATION.

The Royal Society is a very high and mighty body and admission to its Fellowship is looked upon by us as a sort of scientific canonization The mystic letters "F. R. S." after a man's name corresponds to the halo around the head which is the symbol of sanctity in sacred art. The election takes place once a year and as many are called and few are chosen many worthy persons suffer bitter disappointment and give way to the wrath which burns even in heavenly souls. And it is likely enough that some of the scientific Peris, who are doomed to stand disconsolate at heaven's gate without being allowed to enter, do well to be angry. For the chosen few are the nominees of a small clique, and in the domain of the medical sciences it is understood that the selection has for years been virtually in the hands of one man, to wit, Sir Michael Foster, M.P., who is the Secretary of the Society. The distinguished Professor of Physiology in the University of Cambridge is, it is true, above all suspicion of unworthy motives; yet he is in a measure human and it is whispered that he has a more sympathetic appreciation of the merits of Cambridge workers than of those who have not had the privilege of sitting at his feet in that ancient seat of learning. Among the fifteen candidates who have found favor in the eyes of the Council of the Royal Society this year there are but two members of the medical profession. These are Dr. C. J. Martin, Professor of Physiology in the University of Melbourne, whose name is known to the scientific world by his researches on snake venoms and toxins and antitoxins; and the redoubtable Major Ronald Ross, who, like Lord Byron, "woke one morning and found himself famous" by his proof of the mosquito theory of the origin of malaria. The epithet "redoubtable" here applied to him must not be taken as meaning that the Major is more ferocious than the average scientific discoverer; but his military title, to which he still clings though he has for some time ceased to be an officer in the Indian Medical Service, by the association of ideas suggests the idea of an even more famous Major, that renowned *soldado*, Dugald Dalgetty. The medical Major has as aggressive a sense of what is due to him as the legendary one; and like that hero he does not allow false modesty to stand in the way of his claiming what he conceives to be his due. It must be admitted, however, that he has been treated by certain rival investigators in a manner sufficient to rouse a meeker spirit than his. An Italian worker whose name is much in the mouths of men in connection with recent researches on malaria is accused of having simply "conveyed" (as the wise call it) Ross's ideas and published them as his own. Then the great Koch has given to the world a number of reports on malaria in New Guinea and elsewhere, in which no mention is made of Ross. In this case however Ross has no more reason to complain than any of the other investigators, Italian, French, American and British, who have been working at this problem in recent years. Molière, it is known, made no scruple of appropriating whatever in the works of his predecessors appeared likely to suit his purpose; and he justified the procedure by the explanation *Je prends mon bien où je le trouve*. The celebrated German researcher seems to act on the same principle. Like a Cæsar of science

> "He doth bestride the narrow world
> Like a Colossus; and we petty men
> Walk under his huge legs and peep about
> To find ourselves dishonourable graves."

For "petty" scientific investigators the "dishonorable graves" aforesaid are found in the transactions of medical societies where the fruits of so much labor lie buried in oblivion.

Ross is a good fellow and a conscientious laborer in the vineyard of research. But his work,

valuable as it is, has been done under the inspiration of Patrick Manson who is a man of a much higher order of mind, and is indeed, in his own sphere, a genius. He has the creative imagination which not only forms pregnant theories, but by intuition penetrates to the heart of mysteries that have puzzled mankind for ages. By the guesses at truth which he has thrown out he has already sown seed in various soils that will some day grow and ripen to golden harvests. Readers doubtless remember what General Paoli (as recorded in Boswell's "Johnson") said of Goldsmith: *Il est comme la mer; il jette des perles sans s'en apercevoir.* This happy phrase might be applied to Manson. He scatters his ideas about without reserve and rejoices to see them grow to the enrichment of other men's fields. The other day at a meeting of our principal society, the Royal Medical and Chirurgical, he with characteristic modesty described his own share in the business by saying that he had not discovered the cause of malaria but he had discovered Ross. Manson was elected into the Royal Society a year ago, and now the admission of Ross to that august body may be taken as having set the seal of official consecration on the malaria discoveries.

But it is right to recall in this hour of triumph of the mosquito theory that for years Manson was ridiculed as a mere dreamer and a weaver of brain cobwebs. The "superior person" sniffed at him; the laboratory pedant shrugged his shoulders half in pity and wholly in contempt at the mention of his name, and the martinets of professional discipline shook their heads about him. Yet undiscouraged by the disapproval, open or veiled, of the "leaders of the profession" and indeed to a large extent unconscious of it, Manson held stoutly on his way. In season and out of season he preached his gospel, urging that the study of tropical diseases was a matter of vital importance in relation to the expansion of the British Empire; that men who go out to the Colonies to do battle with strange forms of disease should be trained beforehand for the task instead of having to learn their business by experience reinforced by human sacrifices. For a long time his preaching had no appreciable effect. But when the whirligig of politics brought Mr. Chamberlain to the Colonial Office, Manson found a disciple who saw the direct bearing which his teaching had on successful colonization, and the power of spreading the new gospel by the administrative pen—and perhaps uncharitable persons might say, by the sword. Manson was appointed Medical Adviser to the Colonial Office, and soon he became transfigured in profession opinion from a voice crying in the wilderness to a leader in Israel. By his influence the London School of Tropical Medicine was founded. Though very inconveniently situated, far away in the wilds of dock-land, and though cramped for space and crippled by insufficiency of funds, the School has from the beginning made steady progress. The May session commenced with twenty-two students, several of whom belong to the Colonial Medical Service, while a fair sprinkling come from Switzerland, Norway and the United States.

There is another school of tropical diseases in Liverpool of which Major Ronald Ross is the presiding genius. It has the advantage of organic connection with a school of general medicine, and of a convenient situation in a great seaport where ships bring merchandise, and with it consignments of exotic disease, from all parts of the world. It has further the immense advantage of a tutelary millionaire who not only lavishes money on the school, but organizes scientific expeditions to the most distant parts—all to the greater glory of the school and indirectly of those who work the machinery.

The rivalry between the London and Liverpool schools which at first was hidden in the decent obscurity of polite formulæ has now become open and acute. Last summer, as you know, the London School sent two men to live through the malaria season in the Roman Campagna, and protected by an armor of wire-netting to defy the deadly *Anopheles*. Now Liverpool is about to go one better, and an experiment is to be made on a "gigantic" scale to show that a large town can be swept clear of mosquitoes, and consequently of malaria, and kept so. Major Ross some time ago delivered an address in which he spoke as if he could deal with malaria as Defoe, in his *Short Way with Dissenters,* proposed to do with religious non-conformity. All that need be done was to destroy the mosquitoes by poisoning the puddles in which they breed. The method was so simple that it reminded one of the instructions given in the *Georgics* how to suppress a battle among bees, *pulveris exigui jactu.* The idea is not original for the method has been tried at Sassari and one or two other places in Italy with encouraging success; but it has not yet been put to the proof on a large scale. The result of Ross's experiment will therefore be awaited with great interest. In carrying on his campaign against gnats he will not be hampered by want of the sinews of war. It is announced that a large sum sufficient to pay the expenses of one year's trial of preventive measures in some large malaria-haunted city has been placed at his disposal. This will make it possible to maintain a staff of workers with all necessary appliances for that period. They will attack all kinds of mosquitoes to be found within the area of the city and some distance beyond it. They will destroy the adult insects found in the houses and the larvæ found in puddles or vessels of water outside. It is hoped that well-sustained efforts of this kind will reduce the whole number of mosquitoes in the selected town sufficiently to induce local Governments to adopt similar measures in other malarious towns in British possessions. The experiment will be commenced almost immediately. The selection of the town will depend largely upon the degree of assistance promised by the local authorities.

It was hinted in a previous letter that certain of those whom the king had delighted to honor for their services in South Africa were disposed to think His Majesty had scarcely honored them enough. This grave failure of royal recognition has now been rectified in the case of one of the aggrieved ones. Mr. Frederick Treves was a few days ago made by the King a Knight of the Royal Victorian Order, and he is henceforth entitled to all the privileges of the exalted rank to which he has been raised. Mr. Justice Shallow was, as he tells us, "a gentleman born . . . who writes himself *armigero;* in any bill, warrant, quittance or obligation, *armigero*." Sir Frederick can do more: he can, if he will, write himself *eques auratus;* and the adjective would have a special significance as applied to the new medical knight for no members of his profession has won more golden opinions from his brethren, or more samples of the gold currency of this realm from the British public.

It may be added that Treves was Surgeon to the King when Prince of Wales and not long ago he was gazetted one of His Majesty's Honorary Serjeant Surgeons. This office or rather title was, I believe, especially created for MacCormac and him. Lord Lister holds the ancient office of Serjeant Surgeon, the incumbent of which in old days was expected to accompany his sovereign into battle. Among other novel features in the list of Court Appointments it may be pointed out that the name of Sir Felix Semon, the Laryngologist, figures in the list of Physicians Extraordinary; and there is a special office of Honorary Anesthetist to His Majesty which is filled by Dr. F. W. Hewitt. Whether any special significance is to be attached to the creation of such an office, I cannot say. It is probably merely ornamental, and given as a reward for special service like the title "Physician Accoucheur to the Queen," which used to be given to distinguished obstetricians long after Her late Majesty could have had occasion for their professional services. The inclusion of a specialist among the physicians, however, has caused a good deal of what Macbeth calls "curses not loud but deep" among the bigwigs of the College of Physicians who do not like this official recognition of what they regard as a lower grade of practice.

Among the public Semon's appointment seems to have given rise to an absurd rumor that the King is suffering from cancer of the throat. One hears this everywhere—from members of Parliament, from Editors of leading papers, from quidnuncs at Clubs, from gossips of all sorts and conditions, both within and without the sacrosanct pale of "society." There does not appear however to be a shadow of foundation for the report, and Sir Felix Semon's attendance on the King has, it may be surmised, much more to do with cards than with cancer.

In connection with the King it may be mentioned that His Majesty has just consented to become Patron of the British Medical Association. At the last annual meeting of that body held at Ipswich the Prince of Wales, as he then was, was elected an honorary member. As the official wheels of the Association grind very, very slowly the diploma of Membership was never delivered to him, and when he came to the throne he sent a curt intimation that he could not retain the honorary Membership which had been thrust upon him when he was still, in a legal sense, an ordinary mortal. The fact that he has graciously consented to extend his royal patronage to the Association will be highly gratifying to its Members, for in this country a divinity doth still hedge a throne, and the patronage of royalty is considered a most valuable asset by all public bodies and institutions.

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

PUBLIC LAUNDRIES—MOSQUITOES IN PARK FOUNTAINS — KERATOMYCOSIS — OXYURIS VERMICULARIS AND APPENDICITIS—FOREIGN BODY IN THE BRONCHI—FRACTURE AND MASSAGE—ANTERIOR MEDIASTINOTOMY—PUERPERAL SEPTICEMIA—EPIDEMIC CEREBROSPINAL MENINGITIS—VARIOLA IN THE NEW BORN—SCIATICA AND COCAINE.

Delorme, at the Académie de Médicine, April 9, 1901, read a paper on the economic and hygienic relations between public laundries and public health, endeavoring to show that henceforth one may safely put the linen of those suffering from contagious disease among that of healthy people, provided it undergoes the bleaching processes usually followed in these places. Careful examination of the water used in bleaching linen even if infected with various toxic germs, like the streptococcus, staphylococcus, etc., with repeated cultures from them showed that the germs were killed in the process.

Debove, at the session of April 16th, discussed the presence of the mosquito larvæ in the water of park pools and fountains. The prevention of this lies in maintaining a rapid evacuation of the water, never letting it stagnate or in covering its surface with a layer of petroleum oil which will kill the larvæ.

Panas, at the session of April 2d, presented an article in behalf of Collomb (Geneva) on a case of corneal infection by the *aspergillus fumigatus*. Such corneal disease is very rare, since only eight cases are on record, which includes that of Collomb. In almost all, the patients were young laborers who became infected by the pene-

tration into their eyes of dust from the ground or from the husks of cocoa. The corneal ulcer with a typical hypopyon, which might be confused with this condition alone, appears to afflict the older patients, especially if the conjunctiva and lachrymal passages are the seats of a chronic inflammation. In keratomycosis the ulcer usually occupies the center of the cornea and at its own middle presents a greyish-yellow core which is adherent and very hard to detach. Its elimination is slow and one observes about the line of separation no fistulous tract so common in the serpigenous ulcer. Although the pain of this affection is very considerable, its prognosis is very much better than is that of *ulcus serpens,* because it is never accompanied by a purulent degeneration or a general destruction of the eyeball. The one permanent damage to the eye following this disease is a corneal scar of greater or less depth and extent.

Moty (military surgeon) noted the relation between appendicitis of an obscure origin and the *oxyuris vermicularis,* with the conclusion that they are quite frequently found in the organ. In order to detect their presence the appendix should not be washed, but should be immediately opened and carefully inspected, when the nematode will easily be found. Cold water will kill and deform them. In three out of five cases of appendicitis of unexplained origin recently operated on by him he had not the slightest difficulty in demonstrating the worm in the cavity of the viscus. The lesson taught he thinks is that vermicide catharsis would be a valuable treatment in the early medicinal management of appendicitis of unknown cause, and always when worms are suspected anywhere in the intestinal tract.

Piéchand (Bordeaux) communicated an observation of an child three and a half years old who had swallowed a steel nail two and a half centimeters long. Radiography showed the nail lodged in one of the bronchi. The trachea was opened and a steel sound very cautiously passed down to the neighborhood of the foreign body and then a strong electro-magnet was attached to the sound. In a moment the sound was withdrawn and the nail was found attached to its extremity. The little child is to-day perfectly healthy and happy, without any sequelæ of its accident.

Lucas-Championniere presented a thirty-eight year old woman who had received a complete fracture of the left humerus and was successfully cured by mobilization without apparatus. Under massage the pain which had been very active, decreased, the muscular spasm vanished, and the overriding of the bones was greatly corrected, so that to-day her arm is not deformed and is a thoroughly strong and useful member although only thirty-eight days after the injury.

Quénu, at the Société de Chirurgie, March 27, 1901, in discussing the paper of Ricard at the former meeting on the subject of anterior mediastinotomy, said that he would endorse such operative interference by this unusual and highly dangenerous route of approach for the removal of a foreign body lodged in the trachea or bronchi provided it was not accessible by any other route especially the natural. But as to the precise technic to be followed, he could not quite agree with the steps detailed by Ricard in his extraction of a tube lodged at the bifurcation of the trachea and in the mouth of the right bronchus as described at the last sitting. After numerous experiments on the cadaver he has concluded that a posterior mediastinotomy will be far preferable to that of Ricard, the anterior, and for the following reasons. Aside from the intercostal vessels which are negliable there are no large blood vessels encountered except the azygos veins and their confluence. This is significant when compared with the many large trunks in and around the anterior approach. Considerable space can be gained by liberal resection of the ribs and the deep field although far removed from the surface finally exposes the soft median posterior area along the trachea through which the foreign body can almost always be felt and directly exposed and removed. In his attempt to do this Ricard in the anterior field utterly failed.

Tuffier gave as his opinion the wisdom of always using a guide in any mediastinotomy a large radioscopic projection of the patient's mediastinum and the situation of the foreign body.

Kochard reported for Faure, seven cases of puerperal septicemia operated on by hysterectomy, of which he is a firm partizan especially by the vaginal route. In order to obviate the friability of the septic uterus he employs cystforceps instead of the ordinary type and finds that they are a means of saving time. He has been able to remove the uterus thus in from four to fifteen minutes. Of these seven, six patients died, as they were operated on too late but the last fully recovered, because she was brought to him much earlier in the disease.

Netter, at the Société Médicale des Hopitaux, March 29, 1901, spoke of the remote and immediate results of epidemic cerebrospinal meningitis and raised the point whether or not any of the destructive nerve lesions seen after it may arise after convalescence has been apparently complete. This important question can be answered by a careful comparison of the various epidemics of this disease of the past, wherein may be found many examples of absolute and complete recovery and many of damaged sight, hearing and muscular power, shown in paralysis, atrophy and contractures and lastly of impaired intelligence. But a more satisfactory answer of the problem will be a reference to the cases of the present time in which an actual purulent exudate upon the surface of the brain and spinal cord, can be established by lumbar puncture, especially when often repeated. In May, 1900, he observed seven cases of the disease, among which three were followed by loss of vision and four recently seen again were completely cured. During the fol-

lowing three months, June, July and August, 1900, he again saw three cases whose disease went on to complete recovery. Here then are seven cases whose cure has remained absolute for a period of many months after the disease. This final integrity of the entire cerebrospinal apparatus has after all no remarkable features, although one has been able to prove abundant purulent exudate upon the membranes, when compared with the remarkable and final recoveries from purulent pleurisy.

ROGER stated that he had recently had occasion to observe eleven women who were pregnant and at the same time suffering from variola, but went on to full term or very nearly full term. The infants at first sight appeared normal or nearly normal, but on taking their temperature one found that they were all hypothermic. The thermometer in fact did not in any one register over 37° C. and most frequently was 36° C. In one case it was as low as 31°, 30° and even 28° C. Three of the children died respectively four, six and eleven days after birth without having shown any symptom except the low temperature and jaundice. Another child presented moreover a scarlatiniform eruption on the eve of its death. In seven of the cases the development was more frank and really went on to the true variolous eruption. This was ordinarily accompanied by a rise in temperature which went above the normal. On the following day a few discrete scattered vesicles appeared filled with a thick fluid and rapidly desiccating. Death ensued three or four days later with very low temperatures. In one child the temperature fell to 27° C. about two hours before death. The real evolution of the eruption was occasionally like that in the adult. The papules went on to true pustulation. In spite of its gravity the disease was not always mortal because one child recovered although its temperature reached 35° C.

MARIE communicated in the name of GUILLAIN and himself an observation of a patient of thirty-five years afflicted with a moderate sciatica with a well-marked sign of Lasègue. March 26 a small dose of cocaine was injected into his spinal canal resulting in the disappearance within six minutes of the pain. The next day it returned but with much less intensity and then that night disappeared altogether and has since then not reappeared.

SOCIETY PROCEEDINGS.

AMERICAN THERAPEUTIC SOCIETY.

Second Annual Meeting, Held in Washington, D. C., May 7, 8, and 9, 1901.

FIRST DAY—MAY 7TH.

Presidential Address.—This was delivered by Dr. Reynold W. Wilcox, Dr. H. C. Wood being too ill to attend, and consisted of a review of the progress of therapeutics during the last twelve months. This period, he said, had witnessed but few startling achievements in the treatment of suffering humanity, yet a careful review of the vast therapeutic literature gave much satisfaction in that the progress had been of a kind that was likely to be permanent. He referred to the careful study of older remedies and methods, the re-investigation of theories and practices based upon them and the readjustment of their conclusions in the light of these researches. So of the newer additions to their resources, it might be said that to their study was devoted intelligent discrimination, and conservative opinions had been reached as to their value and importance.

For rapid advancement in knowledge and substantial increase in their materials and methods, they were living in an auspicious decade. The therapeutic nihilism resulting from the despair of the dead-house had largely passed away. According to the Teutonic idea, the completeness and conclusiveness of the patient's history was marred by the remoteness of the necropsy report or its absence altogether. While to-day the professed therapeutic nihilist was looked upon as a therapeutic ignoramus they were all somewhat in danger of stepping over the lines of a healthy optimism into the obscurity of an insistent credulity. The society had very properly placed a barrier against the presentation of "secret," patented or copyrighted remedy, remedies, or methods of treatment," by forbidding "paper, report, abstract or other communication, either written or verbal, which directly or indirectly commends or advertises them," and prohibiting discussion upon them, although it permitted adverse action upon these subjects. Thus it was that those substances and methods whose extravagant claims were in inverse ratio to their merits, might meet with their just deserts; others were to be considered *sub judice* until freed from unprofessional restrictions. This stipulation, then, while limiting but slightly the therapeutic resources of real worth, markedly lessened the amount of alleged therapeutic literature which required to be consulted.

Dr. Wilcox then proceeded to refer to the attention which had been devoted recently to internal antisepsis, speaking more or less favorably of the use of chlorine in enteric fever, guaiacol or creosote (particularly as organic salts) in pulmonary tuberculosis, naphtol in various conditions found in the alimentary canal, and various organic bismuth salts in the treatment of the same conditions. As samples of general internal antiseptics he mentioned chlorine, soluble silver, the salicylates and quinine. The conclusion at which he arrived was that, as a result of the labors of Lister and countless followers, the ideal in regard to internal antisepsis had been nearly attained. Internal antisepsis now rested on quite as secure a basis as did the surgical when the pioneers began their work, and the ensuing three decades (it was thirty years since this work was

begun) would doubtless bring to fruition their most daring hopes. As the surgeon gave credit to Lister, so much the therapeutists acknowledge their indebtedness to Bouchard for many of their facts, trusting that others would continue the work that he so painstakingly had begun. At this time they could safely say that internal antisepsis was more than the dream of the theorist. Internal antisepsis, it was possible, might be useless or detrimental, under certain conditions, or might be absolutely contra-indicated because of the patient. How best to attain it was a question to which the answer would vary with each succeeding year as their knowledge of infectious diseases and the best way of combating them rested upon a broader and more secure foundation.

The Corning-Bier method of producing anesthesia by cocainization of the spinal cord was next discussed, the untoward symptoms that result apparently from the toxic action of the cocaine being noted. There was also the danger that the anesthesia might persist for a very long time, or on the other hand that it might be found impossible to produce sufficient anesthesia for purposes of operation, when general anesthesia would have to be resorted to. Permanent disability, so far as he could ascertain, had not been reported. The field of its employment would seem to be as a palliative measure in operable neoplasms producing excessive pain. In obstetrics its use had been successful, both in relieving pain and in not interfering with the usual course of labor and subsequent recovery. In general surgery, the question was still open for discussion, for its advantages were not demonstrably greater, nor its safety necessarily more pronounced than was general anesthesia, while the fact that the patient was conscious during the operation might be a decided objection.

Touching next upon the electric-light bath, Dr. Wilcox remarked that various observers had found it the most satisfactory and efficient of all methods of inducing perspiration, inasmuch as it was a direct stimulant to the gland. Its peculiar value was due to its efficiency as a source of radiant energy which was not communicated to the skin by convection, the skin and all living tissues being like the air in respect that they were to a large extent transparent to radiant heat. Another advantage of this bath was that it encouraged heat elimination and the excretion of effete matters, and that, the temperature of the blood being elevated, there was a quickening of all the vital processes. It was claimed that this method was particularly valuable in the treatment of cardiac disease and in diabetes, while it had also been found useful in dropsy, chronic dyspepsia, chronic malaria, syphilis, rheumatic affections, anemia, etc. A local application followed by an ice compress was almost a panacea for the pain of sciatica, and it had likewise yielded excellent results as a nerve tonic in the treatment of neurasthenia. The Finsen light and the Roentgen-ray treatments were also reviewed. The speaker, however, thought that the claims of the latter in regard to the treatment of certain forms of tuberculosis required more time for absolute demonstration.

Sodium cacodylate, Dr. Wilcox went on to say, had probably attracted more attention than any one other remedy. It could apparently be safely introduced into the body in much larger doses than its arsenic content would lead them to suppose, and could even be administered subcutaneously, although there was considerable dispute as to the agreeableness of this method of administration. It had received favorable commendation in the treatment of tuberculosis, anemia, and other diseases and conditions. Adonidin had been favorably reported upon by one observer who said that it could be safely administered in certain circumstances when digitalis, if used at all, ought only to be used with the greatest caution.

After speaking of other remedies, Dr. Wilcox condemned the use of carbolic-acid solutions as moist dressings, and said that carbolic acid in any strength should be included in the list of those drugs which could only be procured by the prescription of a physician. When alcohol was used as an antidote to carbolic acid, it should not be forgotten that promptness of action was of the utmost importance. Since 60 grains of carbolic acid almost always proved fatal and the drug could be easily obtained, a knowledge of the antidotal power of alcohol should be disseminated as widely as possible among the people.

The serums, suprarenal extract, apomorphine, salol, and other drugs, having had their claims examined, Dr. Wilcox took up the subject of drug standardization, showing the advantages that would be derived from it. He then remarked on the fact, which he considered gratifying, that hydrotherapy was now being investigated by experienced and trustworthy observers. He also paid a brief tribute to the excellent work that was being done in the laboratories of the principal medical schools as well as in those under the control of private enterprise. Paying his compliments to the fad known as "Eddyism," he expressed his regret that it had not borne fruit either in the way of affording material for the study of the natural history of untreated disease, or of ridding them of patients they could not cure —those who had nothing the matter with them. In connection with this part of his subject he made note of the fact that when their own interests were affected the Christian Scientists acted very much like other people, instancing the recent proceedings before the New York legislature, when they resorted to the customary methods for influencing legislation, and carried them out with such prodigality that the unusually callous and corrupt legislators were astonished. Their brazen effrontery, however, he added, was likely to result in the political death of those who had participated in their bounty. He concluded by alluding to the importance of the work being carried on by the committee entrusted with the revision of the Pharmacopœia and of that in

which the Therapeutic Society was engaged.

A business meeting of the Society was afterward held, the proceedings being conducted in private.

SECOND DAY—MAY 8TH.

The Secretary, Dr. Noble P. Barnes, read a letter from Dr. Eli H. Long of Buffalo expressing regret at his inability to be present, and suggesting that at next year's meeting there should be a symposium on therapeutic teaching.

Suggestions Concerning the Use of the Metric System in Prescription Writing.—A paper thus entitled was read by Dr. Francis P. Morgan of Washington who pointed out the ease with which the metric system could be learned by students, and also the convenience it possessed for the practitioner when once he had become familiar with it. He admitted the hopelessness of getting the approval to the proposed change of those who had been so long accustomed to another system. It was all the more important, therefore, that the advocates of the metric system should impress their views on authors and teachers, and endeavor to convince them of the advantages of the system, the chief of which were its extreme simplicity and uniformity. Some text-books had made the concession of giving doses in metric terms as well as in those of apothecaries' weights and measures, but they were given in such a complicated way as to be confusing and practically useless. This was due to the fact that the authors, being desirous of giving the doses in both systems, took those of the apothecary system and translated them literally into decimal figures, the result being a long string of figures which were of no use, and had a very puzzling effect on the student and practitioner who wished to make use of the system. All doses could be well enough expressed in one or two figures, without this apparent desire to attain accurate equivalents of apothecaries' weights and measures.

Dr. Leon L. Solomon of Louisville endorsed everything that had been said as to the advantages of the metric system, but said he thought the doctors were not so much to blame for the continuance of the present practice as was the Government, which ought to have the courage to stamp the Pharmacopœia with its approval, and insist on all medicines being weighed and measured by the same standard.

Dr. Thos. E. Satterthwaite of New York remarked that there was no doubt that the metric system was the most scientific, but there were difficulties in carrying it out, among them that of getting pharmacists to fill prescriptions in accordance with their exact terms.

Dr. Solomon said it was as easy to teach pharmacists as it was to teach doctors the metric system.

Dr. Satterthwaite explained that he did not mean to cast any reflection on the pharmacists; all he intended to say was that they were not taught the metric system.

Others who took part in the discussion were Drs. Wm. M. Sprigg and Robert Reyburn of Washington, Dr. A. C. Barnes of Philadelphia, and Dr. Stewart of New York, all the speakers expressing more or less approval of the metric system.

Revision of Pharmacopœia.—The Chairman, Dr. Wilcox, on behalf of the Pharmacopœia Committee of the Society, reported that the work of the Revision Committee was in a very satisfactory condition—that many of the matters which must of necessity be first considered, such as questions of atomic weights, temperature at which specific gravity should be determined, etc., had been practically brought to a conclusion. The substances which were to be expurgated had been carefully considered and practically a final conclusion reached regarding them. Of the large number of substances proposed for admission, a considerable number had been provisionally tested, the restrictions imposed by the convention being always borne in mind. It was of interest, in connection with the discussion just closed, to mention that the doses to be introduced for the first time in the next edition of the Pharmacopœia were to be the average adult doses expressed in the metric system, with the approximate equivalent doses expressed in the old system enclosed in brackets. The Revision Committee addressed inquiries to all the State and National medical and pharmaceutical societies, in order to ascertain what substances the physicians desired to be officially recognized and what substances were usually prescribed by physicians. The Committee had left no stone unturned to ascertain what was the general desire as to the substances that should be included in the Pharmacopœia. Any criticisms on the Committee, therefore, would seem to be based on insufficient ground, for it had offered every possible opportunity for the making of suggestions. The work was progressing favorably, and the Committee expected to present the finished work in a somewhat shorter period than was required for the last revision. He added a number of other instances that had come within his notice in regard to the metric system to show that it was gaining favor in other professions and branches of business.

The Relation of the Pharmacist to the Physician, and the Relation of Pharmacy to Materia Medica and Drug Therapeutics.—This subject was discussed at length in a paper by Dr. F. E. Stewart of New York. He concluded by submitting a resolution which, while expressing disapproval of everything tending to create monopolies in medical products and preparations, recognized the necessity of protecting capital invested in the legitimate chemical and pharmacal industries, and therefore the propriety of approving the patenting of processes and apparatus. As an instance he said that the patent on the process for manufacturing acetone-chloroform should be recognized and also the product of such process known as chloretone, but they should not approve

of extending the protection of the patent to the main product, which in this instance was acetone-chloroform. He also thought they should approve of the registration of trade names for brands of products to be used in connection with their generic or identifying names, provided that formulas were published whereby the products might be duplicated by those skilled in the art; otherwise there was danger that the art of preparing them might be lost to medical science and the interests of the public jeopardized in consequence. He strongly urged the Society to take the initiative in the formation of a National bureau for the purpose of regulating the conditions affecting the manufacture and marketing of medical products and preparations, and at the same time securing uniformity in their strength by means of the establishment of standards. Medical men and pharmacists were alike interested in this, and they should coöperate to prevent medicines becoming subject to the control of purely commercial interests.

Dr. A. C. Barnes of Philadelphia said the question raised by the paper was of the highest importance. It resolved itself into this, How could physicians get reliable information about new medical products and preparations? Things were different here from what they were abroad—in Germany, for example, where all such new products and preparations were pharmacologically studied and then placed in the plinics.

Dr. Leon L. Solomon of Louisville thought the thanks of the Society were due to Dr. Stewart for his persistent efforts to get a bureau of medicine established. The last speaker had sounded the keynote of the situation when he said that what medical men wanted was the truth. They wanted the truth, the whole truth, and nothing but the truth. If they only devised means of getting this, it was of minor importance whether the process or the name were patented or not, for sooner or later they would become public property. As an example of the difficulty of getting the truth under present circumstances, he recalled a report made by a certain doctor on vaccine virus, in which there were 99 per cent. takes. The proprietors of the vaccine wanted the additional fact omitted that in 50 per cent. of the cases sore arms resulted. If the report had gone out in the shape they desired it was evident that it would not have contained the whole truth.

Dr. Satterthwaite of New York suggested that the matter referred to in the paper and resolution might with advantage be referred to a committee with a view of the taking of definite action.

The Chairman said the subject came well within the jurisdiction of the Judicial Committee, and on his recommendation it was referred to that body.

The Inertness of Petroleum Compounds When Given Medicinally.—This paper was read by Dr. Robert Reyburn, Washington.

Dr. A. C. Barnes said there was no doubt about the non-absorption of petroleum, but that was not conclusive evidence that it was of no value medicinally. A paper by a Philadelphia colleague, which was published in the Medical News, caused him to look into the subject, and his experience in several cases of tuberculosis convinced him of the value of petroleum, not on account of its nutritive qualities, but because it acted as an aid to digestion.

Dr. Solomon thought the petroleum preparations were of use in so far that they soothed the intestinal mucosa.

Dr. Reyburn, while agreeing with some of the remarks that had been made, said petroleum was not to be considered a substitute for cod-liver oil.

Dr. Stewart remarked that the subject was a good one to refer to the proposed bureau of medicine, and let the manufacturers furnish the funds for its investigation.

Heart Disease.—This was the subject of three papers, the first being by Dr. Thomas E. Satterthwaite of New York, who discussed the therapeutics of chronic heart diseases and their complications. Notwithstanding all the recent advances in cardiac therapeutics (and the changes of the last ten years had been revolutionary), he said they were less and less disposed to cry up special remedies for special affections. This was particularly true in valvular disease, where they now placed less weight on the importance of abnormal sounds and more on the attendant phenomena and especially on the character of the lesions behind the sounds. The gravity of the lesion was not always measured by the intensity of the sound. A loud and harsh murmur was not incompatible with an average length of life, whereas a valve might be almost occluded, as in mitral stenosis, without giving an recognizable auscultatory sign. With the best opportunities and the largest experience one was not always able to distinguish between a functional and an organic murmur. Again, single valve lesions were the exception rather than the rule, and there were, besides, frequently complications which made diagnosis difficult from auscultatory signs alone. Recent changes in treatment he summed up thus: The idea of complete rest had been supplanted by rest alternating with bodily activity; venesection by determination of blood to the surface through resistant exercises and carbonated baths; hydrogogue cathartics had been replaced by stomachics and mild alteratives and diuretics; heart stimulants by general nerve stimulants or sedatives, alteratives and nutrients; while drugs of the digitalis group were utilized chiefly for their diuretic action in renal complications, mainly parenchymatous, nephritis or abdominal dropsy. Drugs of the digitalis group, including strophanthus, convallaria and adonis, were always uncertain and therefore dangerous, and should only be employed either when other remedies were inadmissible, or in kidney or liver complications for brief periods, or where nothing more was possible than a brief prolongation of life.

Dr. Wilcox said that in the masterly review of

the subject the author had given them there was one point he had not mentioned, though he had dealt with it in a separate paper some time ago, and that was that in the treatment of cardiac diseases, they were traveling further and further away from the idea of inflammation, and paying more attention to degeneration. The value of rest could not be denied, but the importance of alternating exercise with it could not be too much insisted on. He agreed with the author that they should be more careful than the average doctor was in the use of drugs.

Dr. Solomon maintained that digitalis should still occupy the front rank in the treatment of chronic heart disease, and certain manufacturers were now testing it in such a way as to ensure its uniform strength.

Dr. E. M. Houghton of Detroit said he had been engaged in experimental work on animals with drugs of the class referred to, and the result was to show that they had not the gastro-intestinal irritating effects that were generally attributed to them. His experiments were still in progress; when they were completed he would be pleased to report the conclusions at which he arrived.

In replying on the discussion Dr. Satterthwaite said it was only fair to admit that many good men used some of the drugs of which he had spoken with scant approval.

Dr. J. N. Hall of Denver reported two cases of Aneurism treated by Wiring and Electrolysis, and a paper by Dr. Eli H. Long of Buffalo, on "Principles of Cardiac Therapeutics in Recent Valvular Disease," was read by a substitute, the author being absent.

Third Day—May 9th.

Election of Office-bearers.—The election of office-bearers resulted as follows: President, Dr. Reynold W. Wilcox, New York; First Vice-President, Dr. Howard H. Barker, Washington; Second Vice-President, Dr. Thomas E. Satterthwaite, New York; Third Vice-President, Dr. Leon L. Solomon, Louisville; Secretary, Dr. Noble P. Barnes, Washington; Recorder, Dr. William M. Sprigg, Washington; Treasurer, Dr. John S. McLain, Washington; Curator, Dr. George C. Ober, Washington.

Next Meeting.—It was decided to hold the next meeting in New York on the second Tuesday in May and following days.

Bureau of Materia Medica.—On the recommendation of the Judicial Committee, it was resolved to act upon the suggestion made by Dr. F. E. Stewart on the opening day of the meeting by appointing a committee of three, with Dr. Stewart as chairman, to consider and report upon the question of establishing a bureau of materia medica.

Therapeutic Value of Hypnotism.—Dr. Francis H. Miner, Washington, gave a practical demonstration. The subject upon whom his experiments were conducted was a boy of seventeen, who had been a typical cigarette fiend, but who had been cured by means of suggestion under hypnotic influence. At the close of the demonstration, which included illustrations of so-called psychic blindness and psychic deafness, as well as the more common exhibitions of the influence exercised by the hypnotist, and which was watched and listened to throughout with marked interest, Dr. Solomon asked whether the so-called hypnotic subjects were usually of the class of the boy before them. Dr. Miner replied in the negative, but the other types refused as a rule to come before a medical body for purposes of demonstration. Dr. Solomon further inquired whether hypnotism brought the doctor into good or bad repute. Dr. Miner thought its tendency was to bring the doctor into bad repute. In fact, until the public became educated on the subject, hypnotism could not be used without endangering the reputation of the doctor. Dr. Solomon said he had had some personal experience which was of interest. He made it a point to avoid using hypnotic influence, but on one occasion he had under observation a young gentleman, a lawyer and a man of superior parts, who knew that he (the doctor) could hypnotize. On one occasion he said to his patient quite incidentally, and without the remotest intention of exercising the influence of suggestion, "This medicine I am about to give you will cure you of your smoking." The young man protested that he did not want to be cured of smoking, and said that he would as soon die. Nothing more was thought of the matter until ten days or so afterwards, when the young man called him up on the telephone and complained bitterly that he had taken advantage of him. All desire to smoke and ability to smoke had departed from him, and he wished to get out of the spell. Afterwards at a dinner the young man sent to him asking permission to smoke a cigar. The case was peculiar because he was the only man he had met who was above the general average of hypnotic subjects.

Dr. T. L. Coley, Philadelphia, recalled the fact that Charcot, of Paris, after being a great believer in the therapeutic value of hypnotism, modified his views very much, largely in consequence of finding that he was so often imposed on by his subjects.

Dr. Wilcox, speaking from his own experiences in connection with Charcot's experiments, said he was unfortunate in having as subjects only a number of very excitable and neurotic young women. It was difficult to avoid being deceived, especially when one had subjects of this kind. Dr. Wilcox said he would never hypnotise a patient because, in the first place, of the peculiar reputation it gave a medical man, and secondly because several patients who had come under his observation after being hypnotised showed symptoms of vitiated will power.

Trade and Scientific Names of Drugs.—Dr. A. C. Barnes, Philadelphia, called attention to the fact that the next two items on the pro-

gramme, "Therapeutic Use of Chloretone," and "Heroine in the treatment of Opium Habit," dealt with drugs which were spoken of under their trade names. He did not think it would be right to allow the discussion of the preparations referred to under such names. It was to be remembered that the society was composed of a body of scientists, and all matters that came before them should be discussed on their scientific basis and under their scientific nomenclature. He suggested and in fact was prepared to move a resolution providing for the adoption of this course at all future meetings. Unless such a rule was laid down the Therapeutic Society would be in danger of getting a bad name and of having undesirable uses made of it.

Dr. Solomon said he was prepared to second such a motion. Dr. Satterthwaite inquired whether the adoption of the motion would prevent the reading of the papers.

Dr. Barnes said that was not his wish. They had on the program two papers by very competent men, and his motion would not interfere with their being read. He simply wished to provide safeguards for the future.

Dr. Stewart repeated and emphasized the remarks he had made on the previous day as to the necessity of distinguishing at these meetings between the scientific and trade names of products and preparations. Of course he did not wish to reflect on any of the manufacturing companies, but on the other hand he did not wish to show partiality for any firm's products. All must be treated on their merits and under their scientific names.

The Chairman said he understood the object was simply to get the matter into proper shape. He was sure there was no desire to discriminate in favor of or against any one.

Dr. Barnes said that of course he had no desire to be discourteous or to reflect on any one. They all, however, wanted to make the Therapeutic Society a scientific body. Commercial interests were of great importance in the advancement of therapeutics, but they ought to insist on only the scientific phase of the subject being considered there.

After some further discussion it was decided to pass a temporary rule providing that papers referring to particular drugs should only be read when these drugs were referred to under their scientific names.

Dr. Houghton was accordingly requested to use the term acetone-chloroform in lieu of chloretone, which he did, though he explained that it had been called chloretone in order to distinguish it from other preparations derived from acetone and chloroform. It might, he suggested, be still more correct to speak of the product by its chemical designation of trichlor-tertiary-butyl alcohol. He then proceeded to review the reports which had been made by impartial observers, all going to show that the drug was useful as a hypnotic, local anesthetic, antiseptic and analgesic.

Dr. Stewart said he thought Dr. Houghton had sufficiently demonstrated the necessity of giving the product a special name, and if the manufacturers chose to donate the name to science he for one would be pleased to accept it, and he thought the society should do the same, just as the British Pharmacopœia did in the case of antipyrine.

Therapeutics of Alcohol.—Dr. Leon L. Solomon of Louisville said while showing that men in good health did not require to use alcohol any more than they required to use tea, coffee or tobacco, referred to its use as a medicine in a large variety of diseases with the view of demonstrating that it was of incalculable value, whether used as a stimulant in the ordinary way or as a local application.

BOOK REVIEWS.

The Treatment of Fractures. By C. L. Scudder, M.D. Second Edition. W. B. Saunders & Co., Philadelphia and London.

This work is one which deserves strong commendation. It is not too much to say for it that it is certain to occupy, and deserves, a place in the very front rank of authorities upon this topic.

To the X-ray in fractures a careful study is devoted, with abundant illustrations. Much attention is bestowed upon the anatomical basis for diagnosis, with consequent avoidance of blunders in treatment. There is an excellent and sensible chapter upon the ambulatory treatment of fractures of the lower extremity.

Certain points, though not very many, seem fairly open to criticism; and we think the author will perhaps change his views thereupon with added years. For example (pp. 265 and 279), the advice to measure from the anterior superior iliac spine to the internal malleolus, to determine shortening in fracture of the shaft of the femur. It should be an axiom in surgery not to measure over a greater distance, nor more bones, than necessary; lest the natural difference so often found as to the length of the two limbs deceive. Measurement down to the adductor tubercle or other prominent bony point near the knee is wiser.

Again (p. 83) the assertion that cystitis is always associated with fracture of the spine, and, once more, the statement (p. 304) that fatty embolism exists in every case of fracture, would seem too sweeping.

It would have been well in discussing this last topic to have alluded to shock, and have given the differential diagnosis therefrom.

Upon page 106 is figured, under clavicle fracture dressings, the "Velpeau bandage." This seems to be a modification of the third bandage of Desault; it is certainly neither the position nor the bandage taught by Velpeau.

In the preface the author objects to naming splints of special manufacture, and says such are not described. In general he has followed this laudable plan—with resulting simplicity. However, "Cabot's wire splint" (the book is dedicated to Cabot) is illustrated for various thigh and leg fractures no fewer than seventeen times. And if the Cabot wire splint be discussed by name in thigh fracture, for instance, surely so famous a wire splint as that of Nathan Smith, and also that of Hodgen, deserve at least a mention.

The chapter upon gypsum is the only really weak one. No reference is made to any other plan than that of entirely surrounding the limb, and this, too, is illustrated in eleven cuts.

"Plaster of Paris, when used for fractured bones, is applied either before or after swelling has taken place; if applied before, it constricts the seat of fracture, prevents swelling, and may cause great pain; if applied after the swelling has taken place, it becomes loose as soon as the swelling of the soft parts subsides, and motion of the limb in the splint and of the fractured bones one upon the other is possible" (p. 415). The author is seemingly unaware of the neatest, most comfortable and best of all methods of splinting a leg fracture, namely, that simple modification of the Bavarian splint wherein a plaster sandwich is made by spreading a quarter-inch of plaster cream between two pieces of wet bandage-cloth, to run from toes to knee, up the front of the tibia, but only wide enough to encircle half the leg. This is held in place by a temporary bandage, until it sets, making a perfect mold of the oiled limb beneath; then the bandage is removed and replaced by a few strips of surgeons' plaster. Thus abundant space for swelling is allowed at the back.

In this chapter the author might well have mentioned silicate splints, and the various easy methods of removal of plaster ones. Few will agree with his dictum, "The removal of the plaster splint is difficult. No instrument has been devised that is more efficient than an ordinary sharp jack-knife."

From these random criticisms it must not be inferred that we consider the work unworthy of reliance. On the contrary it is exceedingly able; and the clear demonstration of anatomical guides in diagnosis of fractures at the elbow, wrist and elsewhere, is in itself worth the price of the book.

The number of illustrations—all original—is surprisingly large, and they are exceedingly creditable as to quality and value in explaining the text. To Dr. F. J. Cotton the author gives most of the credit for the artistic work.

Tuberculosis as a Disease of the Masses, and How to Combat It. Prize Essay, Berlin, 1899, by S. A. Knopf, M.D., New York. Published by M. Firestack, 200 West 96th Street, New York.

At the meeting of the "International Congress for the Study of the Best Way to Combat Tuberculosis as a Disease of the Masses," which convened at Berlin, May 24-27, 1899, the sum of 4,000 marks (about $1,000) was donated by two Berlin merchants, lay members of the Congress, as a prize to be offered for the best essay on the subject, "Tuberculosis as a Disease of the Masses and How to Combat It" ("Die Tuberkulose als Volkskrankheit und deren Bekaempfung").

The prize was awarded to Dr. Knopf and this is the successful essay. Those of us who know Dr. Knopf's work will realize that the essay well deserved the prize. At a meeting of the German Central Committee of the International Congress mentioned, it was resolved to publish this essay and arrange for its widest distribution. We are glad to find that Dr. Knopf makes special arrangements for supplying his pamphlet to Boards of Health, Societies, etc., at reasonable rates, for the precious information it contains deserves to be widely disseminated.

A Text-book of Diseases of the Nose and Throat. By D. Braden Kyle, M.D. Second Edition. W. B. Saunders & Company, Philadelphia.

The fact that a second edition of Dr. Kyle's book is called for scarcely more than a year after the issue of the first edition shows how popular this work is. Its popularity seems to be deserved. Treating only of the nose and throat, to which six hundred and twenty pages are devoted, it is very complete. There are 175 illustrations, 23 of them in colors and all of them have a purpose in the book. This second edition differs very slightly from the previous one.

While Dr. Kyle has given due consideration to all the operative procedures in rhinology and laryngology and pharyngology, his book is especially valuable to the general practitioner because of the care with which he goes into details of medical treatment.

There is, perhaps, but one fault that can be found with the book and that is that too many constitutional symptoms and affections of other organs are referred to lesions of the nose and throat, especially the nose. Too many neurotic conditions particularly are attributed to the reflex effect of pathological conditions in mucous membranes. Even this fault, however, is on the right side since the nose and throat specialties have only developed in recent years and the general practitioner is apt to miss the significance of pathological conditions in the upper respiratory tract and their effect on the patient's general condition.

Transactions of the American Dermatological Association. The Twenty-Fourth Annual Meeting, held in Washington, D.C., May 1, 2, and 3, 1900. P. F. Pettibone & Co., Chicago.

The American Dermatological Association always presents some of the most seriously scientific work of the year. The present volume shows

that there has been no falling off in that respect and it contains some excellent papers. The three articles on malignant diseases of the skin, namely, "The Nature of Malignant Disease of the Skin and Its Transitional Form," by Dr. E. B. Bronson; "The Etiology and Pathology of Malignant Disease of the Skin Affecting the Epithelial Tissue," by Dr. M. B. Hartzell of Philadelphia, and "The Treatment of Malignant Disease of the Skin" by Dr. F. J. Shepherd of Montreal, are all very practical presentations of phases of an important subject. They furnish such excellent material for the general practitioner that it seems almost too bad not to have them appear together in some periodical that has a wider circulation than the transactions of the Association. The recent interest in blastomycetes is reflected by a series of papers on this subject.

Pulmonary Consumption, Pneumonia, and Allied Diseases of the Lungs; Their Etiology, Pathology and Treatment with a Chapter on Physical Diagnosis. By Thomas J. Mays, A.M., M.D. E. B. Treat & Company, New York.

This is a book strange of its kind. It might be called unique, for it certainly deviates from many of the fundamental principles now accepted by the majority of physicians and authorities on tuberculo-therapeutics. Take for example paragraph 1, of what the author is pleased to call the fundamental concepts of the work, where he formulates the following proposition: "That pulmonary phthisis in the large majority of cases is primarily a neurosis, and that the pulmonary disintegration is secondary." We cannot agree with this, for the nervous phenomena in phthisis pulmonalis are, in the majority of cases, not primary but secondary. The degree of nervousness does not depend upon the amount of tuberculous disintegration, for it varies in every individual, no matter at what stage of the disease, and in some it is even absent in the earlier stages.

Proposition 2, "That any agent, influence, or condition which undermines the integrity of the nervous system will engender pulmonary phthisis, or some other form of pulmonary disorder" would also be objected to by the majority of physicians familiar with the disease. There are agencies and conditions which may undermine the integrity of the nervous system and still do not affect the condition of the lungs. Acting, public speaking, singing, gambling at the Stock Exchange, etc., are very apt to affect the nervous system of some individuals seriously, and yet they rarely die of phthisis. In sanitariums for nervous diseases pulmonary diseases are relatively rare and, while we are willing to admit that, on the other hand, tuberculosis is frequent in insane asylums, the cause of this should be sought in the usually very crowded condition of these institutions and the presence of a few consumptives who infect the non-tuberculous ones.

Proposition 3 reads as follows: "That the only remedies of value in the treatment of pulmonary phthisis are those which appeal to, and act through, the nervous system." Now, the most important remedy in pulmonary tuberculosis is fresh air, in other words, aerotherapy, consisting in deep breathing, regular respiratory exercises, rest in the open air, sleeping at night with the window open, walking and exercising in the air, etc. It seems that this remedy acts first through the respiratory system, unless we are mistaken it is now the general opinion that air comes perhaps nearer to being called a specific remedy in pulmonary tuberculosis than anything thus far discovered. Tonics and cod-liver oil, indispensable in many cases of pulmonary tuberculosis, exert their beneficial influence through the digestive system by improving nutrition and assimilation.

Dr. Mays is an enthusiast over the treatment of phthisis by silver-nitrate, and he expresses his opinion in this respect in proposition 4 as follows: "That of special value in the treatment of phthisis is the counter irritant action of silver-nitrate introduced hypodermically over the vagi in the neck." Counterirritants will always be of value in the treatment of phthisis, but whether the hyperdermic injection of silver nitrate over the vagi in the neck is superior to the "points de feu" (igni puncture), a good, strong, old-fashioned mustard plaster, or other counterirritants more easily applied, the future work of Dr. Mays will probably decide.

The last proposition (5) "That acute pneumonia and other forms of acute pulmonary disease are closely affiliated with disorder of the nervous system" also deserves some criticism, for experience has taught that people not infrequently succumb to pneumonia who were really known as what are commonly called "people without nerves."

The portion of the book devoted to physical diagnosis is good. It is, however, to be regretted that in a modern book the chapter on infection should so strongly yield to the idea that consumption is not a communicable disease. We do not ourselves like phthisiophobics, but pulmonary tuberculosis must be considered a highly communicable disease. Dr. Mays quotes men who are well known to be antagonistic to the contagion theory, for example, he says on page 203: "Dr. Aufrecht, after referring somewhat extensively to the contagion theory, says . . . . and less justifiable are the reckless conclusions drawn by Koch concerning the etiological indication of the tubercle bacillus." In quoting Dr. Dettweiler, when the latter writes of the freedom from phthisis of those who are engaged in the care of consumptives in the hospital, he forgets to add that the most scrupulous care is exercised with the sputum of the patients, that each one has his individual pocket spittoon, in short, that everything is done to prevent infection of others or reinfection of the patient. At the Adirondack Cottage Sanitarium, one of our most famous and successful American institutions, infection among the

nurses has never taken place, and the physicians and employees explain this solely by the extreme care taken with the infectious sputum. As a contrast to this we beg to refer Dr. Mays to the statistics of Cornet, Kirchner and Debove, showing the unusually great mortality from tuberculosis among the nurses in general hospitals where all classes of patients, including consumptives, are treated. The quotation of cases where contagion had unmistakably taken place is turned over in this volume to favor the nervous theory.

The book does not contain a word of the efficient work of municipal prophylaxis in European cities and in cities of our own country, such as New York, Philadelphia, and elsewhere, and the subsequent reduction of the number of deaths from tuberculosis, nor mentions that in other countries and cities, where such prophylactic measures do not exist (Austria, Russia, etc.), the mortality from tuberculosis is still on the increase. The now-so-absorbing question of State and municipal sanatoria or special consumptive hospitals for the poor does not receive the slightest mention in Dr. Mays' work.

With all due respect for the earnestness and enthusiasm of Dr. Mays as a teacher, physician and writer, the book before us cannot be considered as one up to date.

The American Year-Book of Medicine and Surgery, being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, Collected and Arranged under the General Editorial Charge of George M. Gould, M.D. Volume on Medicine. W. B. Saunders & Company, Philadelphia and London.

This is the medical part of the American Year Book. As is stated in the preface, the experiment made last year in issuing the work in two volumes has proved very acceptable to subscribers and is continued. Dr. Gould announces that the single change in editorship for the present year is the association of the "scholarly pathologist, Dr. A. O. J. Kelly, with Dr. Riesman in the Section on Pathology." Of the review of special subjects, those of Pediatrics by Dr. Lewis Starr and Dr. Alfred Hand, Jr., of Philadelphia, that of the Diseases of the Skin and Syphilis by Dr. Lewis Duhring and M. B. Hartzell of Philadelphia, and the review of general medicine by Dr. Alfred Stengel and Dr. D. L. Edsall of Philadelphia, are especially interesting.

The discussion of typhoid fever contains a very practical résumé of recent investigations of this important disease. The question of the influence of other micro-organisms in favoring infection with the typhoid bacillus, of the possibilities of infection from shellfish, especially infection from eating cockles, and from hitherto unreported sources, are particularly interesting.

In the review of the literature of gastric ulcer it is clearly to be seen that there is a marked difference in the gastric ulcers that occur in the two sexes. Ulcer occurs five times more frequently in women than in men, but while it causes death in less than two per cent. of the women, there is a fatal termination in 17 per cent. of the cases in men. Ulcer, as a rule, also occurs much later in life in men.

Certain phases of syphilis in recent literature are striking. For instance, the impression is gaining ground that inherited syphilis may prove contagious. Fournier reports certain cases of syphilis that proved absolutely obstinate to specific treatment. Syphilis shows a marked tendency to recrudescence of symptoms in the presence of certain contagious diseases, notably influenza.

The chapters on Materia Medica contain some very practical discussions as to the use of new drugs. Sodium cacodylate, for instance, which has attracted so much attention during the past year is discussed in a way to give a very good idea of its present sphere of employment. Urotropin is quoted as having apparently secured a permanent place in therapeutics. The use of gelatin in various ways as a hemostatic and of formaldehyd in various forms as an internal and external antiseptic are other interesting bits in present-day treatment.

It is impossible satisfactorily to compress a year's medicine within so small a compass, but on the whole the American Year-Book forms a very useful review for the busy practitioner of recent advance in medicine. The index to this volume consists of nearly fifty pages and is an excellent list of cross references to the contents of the book. This is a very praiseworthy feature too often neglected.

The International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, Surgery, etc., by Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, M.D., A.M. Volume I., Eleventh Series, 1901. J. B. Lippincott Company, Philadelphia.

Of the three hundred odd pages of the present number of "International Clinics" a little over 100 are devoted to a review of the progress of medicine during the year 1900. This is necessarily crowded and fragmentary, although parts of it are very well done. The first 18 pages of the book are taken up by notes on new remedies. This department is under the care of Dr. Stevens of Philadelphia, whose name is sufficient warrant for the thoroughly practical character of the material to be found in this section.

Among the clinical articles there is an especially good one on gonorrheal rheumatism by Campbell Williams, F.R.C.S. Dr. Williams calls attention to the fact so often missed that the inoculation which produces gonorrheal arthritis

may result from an abrasion of the fossa navicularis caused by the introduction of a sharp-pointed syringe, or from a minute laceration of the urethral mucous membrane due to the passage of instruments.. In two severe cases of urethral arthritis, as Dr. Campbell prefers to call it, he has seen the onset of the disease follow very shortly after acupuncture for preputial edema.

There is an excellent review of the subject of spinal anesthesia by Dr. A. Doleris, accoucheur to the Boncicault Maternity of Paris, as far as this procedure is applicable in obstetrics. He has used it now in twenty-five cases, ten primipara and fifteen multipara. Cocaine anesthesia has according to him, the following advantages: Absolute freedom from pain from the time the lumbar injection is made, increase in the uterine contractions, quicker labor, increase in the power of retraction of the uterus, and great decrease in loss of blood during delivery.

Dr. W. H. Walmsley, Fellow of the Royal Microscopical Society of London, has a very suggestive article on some practical methods in photomicrography. There are articles by Dr. John Deaver, Professor Hallopeau, Professor Delafield, Dr. Solomon Solis-Cohen and Professor Rodman, that are thoroughly practical in character.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital. Second Edition. Revised and Largely Rewritten. Lea Brothers & Co., Philadelphia and New York.

The Hare's "System" of ten years ago will hardly be recognized in this new edition, so complete are the changes, so extended the dissertation and so complete the redress. The additions alone are sufficient to make a new volume. There are twenty chapters which are here given in general outline: General Therapeutic Considerations by Horatio C. Wood; Prescription Writing by Joseph Remington; General Sanitation by Henry B. Baker; Foods, and the treatment of Obesity and Leanness; General Exercises by E. M. Hartwell; Rest Cure by John K. Mitchell; Electrotherapeutics by A. D. Rockwell; Hydrotherapy by S. Baruch; Climate by S. Edwin Solly; Mineral Waters by James K. Crook; Massage by R. E. Moore; Disinfection by W. M. Coplin; Diseases of the Thyroid and Thymus, Myxedema, Cretinism, Grave's Disease and Obesity by S. J. Meltzer; Chronic Articular Rheumatism, Rheumatoid Arthritis and Gout by James Stewart; Diabetes Mellitus by James Tyson; Diseases of the Blood by Ralph Stockman; Present Treatment of Syphilis by Edward Martin; Treatment of Tuberculosis by Lawrence F. Flick, Scrofulosis by Walter Chrystie and Scurvy by C. E. Banks.

The choice of subjects is wide and the names of the authors are a sufficient guarantee of the character of the mode of treatment. Even a superficial glance through this volume brings into prominence the dominant feature of the work: one that the well-known editor constantly presents, namely, the every-day workability of treatments advocated. Here are no lengthy theoretical dissertations largely padded by quotations from European authors, but concise, practical rules that can be made to fit present-day needs. *What*, *why* and *how* are the questions with reference to the use of drugs that the authors answer—particularly the *how*.

The International Medical Annual. A Year-Book of Treatment and Practitioner's Index. With a Series of English and American Contributors. 1901. Nineteenth Year. E. B. Treat & Company, New York.

Treat's "Annual" is well known and its alphabetical arrangement and concise reviews of practical subjects, give it a place of its own. In the department of therapeutics, a special article has been contributed on toxins and antitoxins by Professor McFarland of Philadelphia and Dr. William Morrell.

The article on tuberculosis in this volume is especially satisfactory. It is written by Professor Charles Ruata of Perugia, Italy, who says: "My aim is to give an answer to the following questions: When a physician discovers a tuberculous infiltration existing in a lung, how long is it since the disease began? How does the specific bacillus reach and spread in the lungs? What is the influence of the specific bacillus on the length of the disease and on death from phthisis? The question of heredity, the question of treatment." The answers to these questions furnish an excellent résumé of the present state of knowledge with regard to tuberculosis.

The article on cancer, by Mr. Keith W. Montserrat, F.R.C.S., is another good discussion of an important subject. In general we can find nothing but praise for this excellent manual, though its brevity necessarily lessens its value in the present large field of medical progress.

SOME FACTORS RELATING TO THE ETIOLOGY OF PROSTATIC ENLARGEMENT.[1]

BY J. BENTLEY SQUIER, M.D.

OF NEW YORK;

SURGEON TO THE ALMSHOUSE HOSPITAL.

EVER since clinical observers of urinary disorders have begun to appreciate the relation existing between prostatic lesions and some urinary difficulties, there has been a deeply-rooted idea that the most common affection, namely, prostatic enlargement is a condition of advancing years. A senile change similar to connective tissue deposits in other organs of the body which make their appearance with old age.

Guyon believed it to be a part of a general atheroma and said, in one of his articles upon the subject, that in his experience "*les prostatiques*" are always of advanced years. "You will not, for example, meet a man of forty years (*quarante ans*) with a true hypertrophy." Opinions of this kind, no doubt, have been inculcated largely by the fact that it is in old age that the symptoms of its effects are most marked, as well as by its appalling frequency at that period of life. When we think that, putting it roughly, one out of every three men has some degree of prostatic enlargement after reaching middle life, and that one out of five has enough to cause symptoms from which he must seek relief, the importance of the condition is manifest.

These figures are somewhat larger than those given by Sir Henry Thompson and Sir Reginald Harrison, but data of this kind are difficult to obtain and often misleading. For instance, Sir Henry Thompson believed the frequency to be one in seven or eight. Messer in one hundred examinations found 35 per cent. abnormally enlarged (1 in 3) Ditue, in one hundred and fifteen workhouse inmates, only 18 per cent. Socin believed the first more nearly correct, accounting for Ditue's low percentage by the class examined. My own observations at the almshouse bear out Socin's idea, but the percentage has been even smaller than Ditue's.

As the above are the authorities from which most statistics have been derived I have quoted them.

Thus, at the time in a man's career when he should do his best work, when he should reap the harvest of his early endeavors, and is looking forward to a comfortable old age, he is suddenly made aware that he is a victim of a disease which, creeping upon him insidiously, saps his vitality, renders him a slave to his bladder, and makes pyogenic infection of his urinary tract with its dire results hang over him like a sword of Damocles, ever ready to fall upon some lapse of surgical cleanliness. Advanced thinkers, however, are beginning to cut loose from the antiquated idea that prostatic hypertrophy is only a senile condition, although many of the modern text-books still cling to it with bulldog tenacity, and are finding facts which show that prostatic enlargement is not a disease of old age, but that its foundation is often laid at the incipiency of a man's sexuality.

It is with this idea in view that I wish to draw your attention to a few remarks bearing upon the subject.

While it is not the writer's intention to enter into a detailed discussion of the anatomy or physiology of the prostate, it may be well to mention a few of the more prominent features. We must appreciate that the prostate is not only a band of muscular fibers concentrically arranged around the bladder neck, but a highly-organized, secreting body partaking of as important a part in the sexual function as any of the various organs which comprise the sexual apparatus.

Three structures entering into its composition may be described, namely, the tubular glands, with their ducts; the smooth muscle forming the sphincter vesicæ internus, and the striped muscle forming the sphincter vesicæ externus. In addition through its walls run the ejaculatory ducts. The glandular elements do not reach full development before puberty and in some the muscular elements predominate throughout life, so that in one person the secreting function may predominate and in another the motor. This difference can be often felt by rectal touch and probably has a direct relation to the variety of hypertrophy which may develop later.

The prostate's part in the physiology of the sexual act is threefold, namely, (1) to close the bladder orifice at the time of ejaculation; (2) to supply a fluid which enters into the composition of the semen, as well as exuding into the urethra before ejaculation, neutralizing any urine which might be in the urethra and by its acidity destroying the activity of the spermatozoa, and (3) to aid in the expulsion of the semen at the climax of the sexual orgasm. All of these functions are to a large extent dependent upon an active congestion of the gland. The swelling of the prostate caused by its increased blood-supply completely closes the bladder opening. This same blood-

[1] Read before the St. Luke's Hospital Alumni Society, Feb. 8, 1901.

supply produces an increased activity in its secretory function. The muscular contractility although centrally produced reflexly by irritation of the glans penis is also brought about by the reflex irritation of the nerve filaments in the prostate due to its distention. It has a dual purpose of aiding in the ejaculation and afterward, by expelling the blood from its dilated sinuses, of reducing its transient hyperemia. With this but meager allusion to the great physiological importance of this organ one can readily perceive how continued practices, perverting its normal function and disturbing its vascularity, will, as is evidenced in other organs of the body, the kidneys, liver, spleen, lungs, etc., eventually lead to interstitial changes causing pathological conditions.

We believe this to be one of the most potent predisposing factors in prostatic hypertrophy. If the sexual history of prostatic cases be carefully gone into, one will find that a surprising majority have abused their sexual apparatus to a greater or less extent and have kept up a constant hyperemia of their prostate for years, through total ignorance of the importance of hygiene in their sexual life. Modern society, with a false modesty, educates its youths in almost everything except giving them a true knowledge of their reproductive powers, and when a boy begin to appreciate that his penis is something more than a water pipe and inquires about it, he is too frequently told that "he must not talk about such things," "that he will learn in time." Not satisfied with this he goes to some friend, possibly only a few months his senior, and is instructed about that function which really is the chief end of man. To use the words of Krafft-Ebing, the function which "forms the most powerful factor in individual and social life. It is a mighty impulse for bringing into action our most effective energies, for acquiring property, for the foundation of a home, for rousing altruistic feelings for a person of the other sex, first, and, later, for one's children, and in a wider sense, for the whole human family."

Let us follow such a boy through his sexual life. He learns to masturbate from the instructions of this comrade and continues the habit for a number of years until he reaches what has been termed the "conscientious age." He now worries lest he has done himself injury and manfully tries to stop it. Suppose now he meets young women who will permit all liberties except the sexual act and the boy, who is now a young man, indulges himself, and unfortunately will take occasion to enjoy such women as often as possible. Such ungratified desire increases his sexual hyperemia and he seeks relief from a physician who advises him to go to women. This he does and, leaving out the question of venereal infection, his condition is aggravated because these embraces are not normal ones. He may or may not be stimulated by alcohol at these times, but he usually tries to perform the act as many times as possible if not for his own gratification for that of his paramour. To go on further, this man marries and for various reasons, financial, social or otherwise, or because that by this time his hyperexcitability produces precipitate ejaculation and he is unable to awaken an orgasmic response in his wife and she, feeling that there is nothing in the sexual relation for her except childbearing, decides not to have children and they adopt withdrawal as a means to the end. This is often done, I am sorry to say, upon the advice of a physician. So the man lives in a state of sexual congestion for a number of years until various sexual neuroses develop which render him more or less impotent. It is for this condition that he usually first seeks medical relief. If you examine him by the rectum you will find a broad, flabby prostate, very tender, and in the region of the verum montanum, exquisitely so. The muscular fibers have lost their tone by the constant overdistention with blood and the glandular elements have become hypertrophied because of the extra amount of work forced upon them. Fluid can be expressed from the dilated acini and although the patient may not complain of urinary symptoms, even at this period questioning will frequently bring out the fact that there is an increased frequency of urination as well as hesitancy in starting the stream. Residual urine is uncommon at this stage, probably because the bladder muscle has not yet lost its tonicity and can overcome the existing degree of prostatic obstruction. While we do not believe that the foregoing history, which is not a hypothetical one, but that of a patient now under treatment, would cover every case of beginning prostatic enlargement, men's sexual lives being too varied to admit of such a possibility, we feel confident that abnormal sexual indulgences which tend to keep up a chronic hyperemia in the gland are more often a forerunner of subsequent enlargement than is senility, gout, rheumatism or atheroma, which are among the "chief causes" given in a popular work recently published.

It is not to be inferred that it is the few acts of masturbation practised by the irresponsible boy, the involuntary sexual stimulation which the healthy man may experience during the caresses of his affianced, or the irregular sexual debauches of a *roué*, which lead to a chronic hyperemia, any more than it is that infrequent alcoholic excesses lead to cirrhotic changes in the liver and kidneys. It is the persistency with which these men carry on these sexual aberrations over a long period of years which eventually produces lesions in the same way that the steady, quiet tippler becomes heir to a hob-nailed liver.

So much, then, for general considerations, but what Americans want is facts, so I wish to place before you some data which have been gleaned from three hundred cases of prostatic

enlargement in which a detailed account of the patients' sexual life has been recorded.

The first hundred have to deal with the condition known as prostatic congestion and the remaining two hundred with true hypertrophy. This distinction is, of course, to a large extent an arbitrary one, the conditions being so closely allied and so often present together that the difference is more of a clinical than of a pathological nature. It has been through the courtesy of Dr. L. Bolton Bangs that I have been able to use these histories in compiling these percentages, they being the records of patients who have been under his care during the past few years.

They represent men of the higher walks of life of almost every profession and it is an unfortunate commentary upon our own profession that so many of its number are upon the list, gynecologists and dentists being most frequently the victims. Some of the patients have been treated for sexual congestion, have been lost sight of, and years later have returned with symptoms of prostatic obstruction. Of the cases of sexual congestion, leaving out those complicating venereal diseases or acute inflammation, there are three abnormal sexual acts which have been indulged in excessively in over 85 per cent. of the patients, namely, masturbation, prolonged sexual excitement without gratification and *coitus interruptus*, also known as withdrawal or frauding. The number of years before their evil effects have become apparent seems to have a direct relation to the physical condition of the patient.

One of the patients was taught to masturbate at six years of age, continued it until he reached his twelfth year, when he began to have coitus. Until twenty-four he continued both when he developed symptoms of impotency. Rectal examination showed an exquisitely tender prostate almost twice its normal size.

The symptoms complained of in these patients have been sexual neuroses more often than urinary difficulties.

In the cases of hypertrophy, *coitus interruptus* has been present in 60 per cent. of the patients, masturbation and dallying in 25 per cent., and but 15 per cent. gave normal sexual histories.

Excessive sexual intercourse has been present to a large extent and especially among that class of patients known as *fraudeurs*. Their ability at first to perform coitus so frequently has been attributed to the fact that the quantity of semen lost is less when this form of coitus is indulged in. The true explanation probably is that they do not relieve their sexual congestion and that their nerve-centers are overstimulated by the peripheral irritation due to this congestion keeping them in a constant state of hanker. Eventually, however, they lose the sexual sense and, as has been previously stated, have their attention first drawn to their condition by failing virility. Many other things produce prostatic hypertrophy which we have not enumerated, it being the writer's intention merely to show the frequency of the afore-mentioned causes in a large number of patients.

In the 15 per cent. of the cases in which no sexual aberration was present there were a number whose primary prostatic congestion was apparently due to a derangement of the portal circulation. They were men of sedentary habits who had suffered from functional or pathological disturbances of the liver.

We are not riding a hobby, as the Germans said of Bergeret, when he first wrote of the evils of frauding, neither are we so dogmatic as to think, with them, that no good can come out of France.

The age when a physician figured only as a healer of disease has departed. Now he instructs how to avoid it and as we have taught people how to live, so that the precautions against many diseases are ordinary household observances, so ought we to teach them the value of hygiene in their sexual relations.

GASTRIC ULCER AND MUCO-MEMBRANOUS COLITIS AT THE PARIS CONGRESS.[1]

BY JAMES J. WALSH, M.D., PH.D.,

OF NEW YORK;

INSTRUCTOR IN GENERAL MEDICINE AT THE NEW YORK POLYCLINIC HOSPITAL AND SCHOOL FOR GRADUATES IN MEDICINE.

Two subjects in gastro-intestinal diseases were selected for special reports and discussion at the last International Medical Congress. These subjects, gastric ulcer and mucous colitis, have attracted considerable attention in the medical world of recent years. It seems worth the while, therefore, to invite further discussion by a brief review of some of the points that seem of special interest.

Gastric ulcer is not nearly so rare an affection as it used to be considered. Not only does it occur idiopathically with much more frequency than was thought, but it forms at times a serious complication in infectious diseases and in diseases of the circulation and metabolism. As the Fenwicks have stated in the preface of their recent book, Ulcer of the Stomach and Duodenum, gastric ulcer is not infrequently the unsuspected cause of death in certain infective complaints and in diseases of the heart and liver.

Despite the recent increased interest in gastric ulcer the etiology of the affection remains a subject of almost as much uncertainty as ever. A number of theories have been advanced to account for its origin and it is possible that most of them describe elements of etiology that act as adjuvant factors in the production of the affection. One thing is certain, ulcers having the typical characteristics

[1] Read before the Section on Medicine of the New York Academy of Medicine, November 20, 1900.

of gastric ulcers occur only at those parts of the digestive tract in which there is free acid bathing the surface of the mucous membrane. These are the stomach, the duodenum and the gastric end of the esophagus. Duodenal ulcers resemble exactly those which occur in the stomach. Ulcerative lesions below the pancreatic duct, where the pancreatic secretion has neutralized the acidity of the gastric contents occur very rarely and are of a superficial character markedly different from the deep erosion which characterizes the gastric and duodenal ulcer. Erosive ulcers occur, however, at the gastric end of the esophagus where the regurgitation of the stomach contents causes the mucous membrane to be frequently bathed by free acid.

There is little doubt that gastric ulcers are due to self-digestion of the stomach wall. The predisposing factor that leads to this self-digestion is in dispute. Such distinguished authorities as Rokitansky and Virchow attributed the digestion of the gastric mucous membrane to a disturbance of the circulation in the gastric mucosa and consequent lowering of the resistive vitality of the tissues. Virchow thought that the disturbance of circulation was due to embolism. He pointed out that the gastric ulcer has many points of analogy with infarct of the lungs. As is well known, however, gastric ulcers occur by preference in the pyloric end of the stomach. Embolism of the stomach arteries occurs practically always at the cardiac end. Experimentally no one has ever been able to produce embolism in the blood vessels of the pyloric region alone, yet solitary ulcers are usually situated here.

Two kinds of change in the blood of individuals predispose them to the occurrence of gastric ulcer. Anemia and the blood disturbance due to an infective condition somewhere in the body. It has been pointed out by Einhorn, I believe, that anemic patients are especially prone to suffer from gastric hyperacidity. Whether hyperacidity exists in infective conditions, or not, remains to be investigated. It would not be surprising, however, to find it. One of the simplest methods of inhibiting bacterial growth is to acidify the medium on which the micro-organisms are growing. It has been pointed out that one of Nature's protective mechanisms against infection is very probably an increase of the acid in the system, because of the effect this has upon micro-organismal growth. The occurrence of gastric ulcer only where free acid occurs and the fact that those who are especially predisposed to its occurrence frequently have gastric hyperacidity would seem to furnish the best clue to the origin of the affection. It is probable that certain irritative and traumatic influences are the immediate and localizing causes and that their absence permits many cases of gastric hyperacidity to run their course without the occurrence of gastric ulcer.

Further study of the affection to be fruitful must take account of one feature of the disease which has thus far been neglected. All gastric ulcers have been grouped under one head. This is rather the chronic form of the affection. There seems to be a distinct nosological entity, however, which may be called acute gastric ulcer. Symptoms of this affection occur almost always without warning. The most characteristic symptom is profuse bleeding. The affection occurs particularly in young women who are confined to the house, domestic servants, governesses, dressmakers and those in whom a sedentary, indoor occupation has induced a condition of anemia. Acute ulcer is noticed not infrequently in infectious diseases. Dieulafoy at the Paris Congress called attention to the frequency with which these ulcers are due to the pneumococcus. In a certain number of cases of death, the result of sudden profuse hemorrhage from the stomach, he has found minute ulcers of the stomach from which pure cultures of the pneumococcus could be obtained. These pneumococcus ulcerations are not necessarily connected with pneumonia nor with any affection of the lungs. As another French observer has pointed out, however, they may occur during pneumonia and then they make the prognosis of the case very unfavorable.

Another interesting form of gastric ulcer is that which occurs during the course of appendicitis. Dieulafoy particularly has called attention to this and the affection is spoken of by French writers as appendicitis with black vomit. It seems almost surprising, when we consider how much attention has been given to appendicitis in this country, that this symptom has not been noted more frequently. Dieulafoy has found that it occurs particularly in cases in which there exists a tendency to systemic infection and he attributes the origin of the ulcer to the change in the blood induced by the septic elements that have found their way into the circulation. We may recall that Von Jaksch called attention to the fact that acute gastric ulcer occurred with special frequency in puerperal women. It is probable, however, in these cases that it was not so much the puerperium that was the causative element in the case, as some one of the infective conditions to which puerperal women are so liable.

Now that the conditions in which gastric ulcer develops are more clearly defined, the prophylaxis of the affection seems worth considering. Gastric superacidity undoubtedly plays an important rôle. To this, the addition of some irritant seems necessary for the production of the ulcer. It is important therefore that patients who are anemic, or who are suffering from subseptic conditions should be given remedies to lessen the gastric acidity, as also the acidity of the blood to which the gastric secretion owes its abnormality. All irri-

tating substances should be carefully excluded from the diet and anemic patients should be warned against the danger of swallowing coarse food, or any sort of food that has not been thoroughly masticated. Needless to say they should be warned also of the danger of even slight trauma of the abdominal walls during the anemic condition.

Gastric Ulcer and Nervous Gastric Affections.—It was a favorite saying of Professor Oser of Vienna that nervous affections of the stomach can and do simulate every form of stomach affection known. This was illustrated very well by the fact that German and French clinicians reported a series of cases in which hemorrhages, sometimes quite severe, had taken place without any rupture of the mucous membrane of the stomach. In two cases at least operations had been performed with the expectation of finding a gastric ulcer. Ewald reported some cases in which he felt sure from the after-course of the disease that the hematemesis was due to nervous conditions and not to any actual erosive lesion of the gastric mucous membrane. In one case at least this opinion was confirmed by autopsy. Nervous gastric crises are now known to occur in many other diseases than locomotor ataxia. The possibility of their occurrence in any given case greatly adds to the difficulty of positively diagnosing ulcer of the stomach except when the course of the disease can be faithfully followed and carefully studied.

Treatment.—The most interesting thing about the discussion on gastric ulcer was the unanimity of physicians and surgeons in the expression of the opinion that surgical measures should be resorted to much more frequently than they have been. Dieulafoy insisted that as soon as hemorrhage becomes profuse enough to be alarming or recurs frequently the only safe therapeutic procedure is to open up the stomach, tie the bleeding vessel and excise the ulcer. Dr. Ewald of Berlin said that he finds himself in the position of having recourse more and more to the surgeon's aid in the treatment of gastric ulcer. If hemorrhage is alarming this is the safest method. Where ulcers prove very obstinate to treatment, however, two things must be borne in mind. First, that recovery by ordinary healing processes in these chronic cases almost inevitably results in future disturbance of stomach function because of contractile deformation of the stomach and interference with its motilty. Second, old ulcers and their scars are especially liable to be the seat of gastric cancer. Either of these sequelæ may necessitate recurrence to the surgeon later in life when the patient's condition is not so favorable for operation and when the prospects of complete relief or ultimate recovery are very much obscured by the complications that have developed. The tendency of modern surgeons is, of course, very distinctly in the direction of more frequent operations upon the stomach for benignant pathological conditions. The statistics of such operations and the relief afforded by them justify the extension of gastric surgery that they advocate.

A series of interesting communications were made to the Congress with regard to the use of olive oil in painful affections of the stomach. Careful clinical observers on both sides of the Rhine (and English medical men have the habit of saying that when observations made on one side of the Rhine are confirmed on the other there is surely something in them) claim that they have obtained marked relief in obscure painful conditions of the stomach by administration of large doses of olive oil. From 100 to 300 grams (3 to 10 ounces) of the oil are prescribed in the twenty-four hours. These large doses of oil seem to have been of special service in cases of gastric ulcer. Strauss of Berlin has seen them do good where all other means have failed and where even rectal feeding had proved unsuccessful. Matthieu of Paris said that he was skeptical as to the effect of the oil when he first tried it, being inclined to think it no more than an old popular remedy become a new fad, but experience proved it to be an extremely valuable therapeutic measure. He always has recourse to this method in obscure gastric discomfort. It was pointed out that the administration of morphine even hypodermically was contra-indicated in these cases because morphine is eliminated by the stomach and its presence increases the gastric hyperacidity already present. Atropine may be used, but there has been need of some simple sedative, such as is supplied by the oil.

Muco-Membranous Colitis.—There is no doubt that this interesting and little understood disease is on the increase in our time. The exact amount of increase is, however, not easy to determine. Statistics will have to be analyzed with great care if the actual increase in the number of patients with the disease is to be found. Mannaberg of Vienna said that in the last three years only twelve cases of the disease have been under observation in Nothnagel's clinic at the Vienna General Hospital. During this same period, observers in France have been seeing hundreds of cases of the disease. At Plombières, a noted watering place in France with a reputation for the cure of the disease, four hundred cases of mucous colitis have been under treatment within a very short time. Mannaberg insists that there are two conditions included under the name mucous colitis, which should be carefully differentiated. These are, first, mucous colic, a painful condition of the intestine followed by stools which contain mucus. The other, a recurring affection of the intestine in which patients' stools contain mucus and shreds of membrane and the general condition is affected. Mucous colic is a pathological incident. Mucous membranous colitis is a path-

ological condition. If mucous colitis were as common as it is reported by French observers there would surely have been many more cases observed in Professor Nothnagel's clinic, for during recent years the investigation of intestinal disease and especially of the stools have been subjects of special study in the clinic. Perhaps the difference in the statistics points to the essentially nervous origin of the disease. The high-strung nervous French suffer very often; the phlegmatic Austrians escape.

Boas of Berlin insisted that mucous colitis has become much more frequent in recent years. He attributes this increase of frequency to two causes. First, the struggle for life has become more intense in our day and the nervous conditions which are practically always the basis of muco-membranous colitis have as a consequence become much more frequent. The second cause, is the present, common abuse of laxatives. Most people consider themselves perfectly justified in treating constipation in their own way whenever it arises and various forms of irritative purgatives are employed in constantly increasing quantities for the purpose of arousing peristalsis. As the constipated habit grows more inveterate the amount of irritation needed to produce evacuations of the bowel must also be increased. In addition to this, the presence for long periods, of fermenting fecal material adds to the irritation of the colon. The consequence is that the chronic condition of nervous hyperexcitability and irritative congestion of the colonic mucous membrane leads to hypersecretion of mucus and to the deposition of pseudomembrane.

Dr. Boas said that some of the difficulty with regard to constipation in our day came from the fact that fats did not enter as plentifully into the modern dietary as they should. The absence of fatty matter in the stools made them more irritating, allowed them to dry up more easily into scybalous masses and in general hindered the natural mechanism for the easy passage of feces through the colon.

The nervous element is evidently the most important factor in the etiology of the disease. A number of observers pointed out its special liability to occur in nervous women and the fact that it sometimes seems to replace symptoms in the genital sphere. One observer pointed out that this proneness of the disease to serve as an equivalent for symptoms in the genital tract was true where the disease attacked men also. Symptoms of prostatism are sometimes replaced by an acute attack of mucous colitis. On the other hand, when the disease occurs in young men it is nearly always in conjunction with sexual neurasthenia and has been known to occur as the result of worry in a nervous individual during the course of a gonorrhea with complications.

The pathological basis of the disease is not known exactly. Fortunately very few patients die from muco-membranous colitis itself. In most of the reported cases where autopsies have been secured no lesions were found in the intestinal tract. Dieulafoy called attention to the fact that if the basis of the disease were a true inflammatory colitis a spread of the inflammation to the appendix might be expected to occur in a certain percentage of the cases. He has never had a case of mucous colitis under treatment in which appendicitis occurred as a complication. On the other hand, he has carefully collated the records of 700 cases of appendicitis that have occurred under his own observation and in but one or two instances was there any history of mucous colitis having preceded the attack. Potain confirmed Dieulafoy's observation with regard to a complete absence of any connection between mucous colitis and appendicitis. If the appendix were liable to be affected in this condition at Plombières, where several hundred cases of mucous colitis are often under treatment, there would be need of a surgeon in constant attendance for consultation in appendical complications. This absence of infective power argues against the existence of any inflammatory condition as the basis of mucous colitis and seems to stamp it essentially as a nervous disease.

Dieulafoy said that patients suffering from mucous colitis who have any anxiety as to the possible occurrence of appendicitis can be given absolute reassurance of their freedom from the liability to appendical complications without any necessity for carrying their appendices in their vest pockets.

While constipation is the prevailing condition between attacks of mucous colitis and especially before an attack, specialists from Plombières declare that there is also a diarrheic form of the disease. This occurs in about one-tenth of the cases. The symptom on which the diagnosis of the disease depends is the presence of glairy muco-membrane in the stools, usually preceded by constipation and accompanied by recurring attacks of pain. The constipation is occasionally absent and the pain also in a certain number of cases. In about eight per cent. of the cases intestinal lithiasis is noted, that is, concretions are found in the stools.

All are agreed that the treatment of mucous colitis must be directed much more to the general nervous condition that to the local symptoms. As soon as the neurotic symptoms begin to disappear the attacks of muco-membranous colitis grow rarer and finally cease entirely. With this idea of the etiology of the affection patients suffering from this condition are advised, country residence, work in the open air and freedom from the strife and anxieties of urban life.

STREPTOCOCCUS BRONCHITIS IN INFLUENZA.

BY F. FORCHHEIMER, M.D.,
OF CINCINNATI;
PROFESSOR OF MEDICINE IN THE MEDICAL COLLEGE OF OHIO, UNIVERSITY OF CINCINNATI.

THE fact that the various forms of bronchitis cannot be classified according to the bacteria found in the expectoration must be admitted without further discussion. While such a classification is very tempting, clinical evidences do not justify any such attempt.

On the other hand, it is the object of this paper to show that streptococci under certain circumstances produce a clinical picture which seems to me to be more or less characteristic. As far as my own observation goes these circumstances consist either in symbiosis, with the influenza bacillus, or as a secondary infection with streptococci, the influenza bacillus being the primary infecting agent.

I am not prepared to state that these are the only conditions that might produce this clinical picture; for it is conceivable that some other symbiotic combination, or streptococcus infection secondary to some other primary infection besides that of the influenza bacillus, might be followed by the same result; but I had not seen this clinical picture before the first influenza epidemic came upon us, and I have since never seen it except in combination with influenza. The subject is of vast importance, not only on account of the frequent occurrence of the clinical picture, but also in relation to differentiation from tuberculosis of the lungs; not a few of the cases which form the basis of this paper having been sent to me on account of the fact that a diagnosis of phthisis had been made either positively or tentatively. All the cases were observed in private practice. I have not included any hospital cases, for the reason that they could not be kept under observation long enough for my purpose. Only such cases are included as I could follow up for at least one year after the attack had passed over. All the cases occurred during the epidemic of 1896, 1897, 1898, 1899 and 1900. None are included that occurred during the epidemic of 1901. In all there are fifty-four cases which were observed.

The reason for calling this condition streptococcus bronchitis is to be found in the fact that in all the cases this lower form of life predominated, and, in quite a number of cases, notably some of the worst, it was the only bacterium that was found in the expectoration. While it has been impossible to fulfil the requisites of Koch as to the pathogenic nature of the streptococci, the constancy with which they are found, and the relative uniformity of the clinical picture, seems to me to make it impossible to use any other term.

The frequency of the occurrence of streptococci in influenza has impressed itself upon a large number of observers, and before the discovery of Pfeiffer some went so far as to consider the streptococcus pyogenes as the cause of influenza.

The streptococcus was found in all the cases; in twenty-three cases it was associated with staphylococci alone; in three cases streptococci, staphylococci and the diplococcus were found, in only one case streptococci and the influenza bacillus; in twenty-seven cases the streptococcus alone was found.

My only experience, as to the frequency of the influenza bacillus in influenza bronchitis does not correspond with that of Leichtenstern, who was able to find it in the sputum for weeks, but with that of Von Jacksch, who has shown that in the epidemics that have occurred within the last four or five years the influenza bacillus has disappeared after a comparatively short time and has been, as it were, replaced by the streptococcus. According to this, then, I cannot speak of a symbiotic process, but must consider the condition a secondary infection.

The age of the patients was as follows: Six between 10-20 years; 14 between 20-30 years; 16 between 30-40 years; 13 between 40-50 years; 4 between 50-60 years, and 1 between 60-70 years.

Under 10 years of age streptococcus infection of the bronchi with influenza is apt to take upon itself a different clinical picture than in older subjects, as has been shown elsewhere,[1] although it occasionally presents the same symptoms as in adults. Conversely, as will be shown hereafter, pseudopertussis is not rare in adults. That streptococcus bronchitis is rare after fifty years is of interest; but longer observation may show that this is due to the comparatively small number of cases observed and, therefore, too much importance must not be attached to this single observation.

There were 24 males and 30 females; inconclusive as to relative sex ratio on account of the small number of cases observed.

The symptoms were as follows: The onset of the disease always follows an attack of influenza, the primary attack being in the majority of cases of the respiratory type, in the minority, of the nervous or gastro-intestinal form. In other words, any form of influenza may be followed by this peculiar type of bronchitis. The symptoms of influenza disappear before the attack of bronchitis develops. This is the case in the large majority of cases; even when we find the respiratory type of influenza, the characteristic symptoms do not develop without a remission of from several days to a week or ten days. Thus, if a patient should have laryngo-tracheo-bronchitis from influenza this condition will have been very much ameliorated before the streptococcus bronchitis develops. Exceptions to this rule occasionally occur, but they are not common. It goes without saying that if the patient be in the period of convalescence from influenza the symptoms of that period will persist. The attack begins rather suddenly, so that in the normal form, *i.e.*, in the most common form, it will be fully developed in from twenty-four to forty-eight hours. The dominant symptom is the cough; always spasmodic, sometimes

[1] Cough in Influenza Simulating Whooping-cough. Archives of Pediatrics, XVII., 11, 1900.

simulating whooping-cough, occurring at night as well as in the day-time, and annoying the patient exceedingly. On account of the violence of the cough the patient complains of headache, pain in the lower region of the thorax and sometimes in the abdominal muscles. For the same reason vomiting occurs, and not infrequently the appearance of the face is the same as in whooping-cough; although this is not so common in adults as in children. The attack of coughing is usually followed by expectoration; the sputum varying from a mere serous through the various grades of mucous and purulent. The amount of coughing is disproportianate to the quantity of expectoration, so that in ten of the cases there was an admixture of blood; in six of these there was bloody mucus, in four unmixed pure blood—in two of the latter apparently independent of the effort of coughing.

Physical examination shows evidences of bilateral bronchitis in the medium-sized tubes, in the moist stage. At times there are evidences of bronchitis of the larger tubes, and in some cases these are always present; but the principal localization is in the tubes of middle size. The larynx is not implicated in the majority of cases; when the trachea can be seen it is not uncommon to find its mucous membrane injected. With these symptoms there is present an abnormality in body temperature. I have seen the temperature as low as 96° F. in the morning, and an evening temperature of from 99 to 100 F. or more (registered under the tongue or in the rectum), and making, therefore, an abnormally great diurnal range. The subnormal morning temperature is apt to be overlooked, because we are in the habit of shaking the register of the thermometer to the arrow and not below it. In children the temperature range is greater, showing an evening temperature of 102 - 103° F., with subnormal morning temperatures not uncommon. Occasionally adults are found with this same range of temperature, except that the morning temperature is not so apt to go as low. The pulse may be abnormally slow, normal or rapid. If the pulse has been slow in the primary attack, which is a very common occurrence, it takes some time before it becomes normal. In a number of cases the pulse is rapid and, as opposed to the slow pulse, the ratio of pulse to temperature is retained; when the pulse is slow it remains so for the twenty-four hours, being accelerated only a few beats by increase in temperature. In those cases that were examined there was found no leucocytosis nor hypoleucocytosis, except in the severer forms when a moderate leucocytosis was noticed, not exceeding 14,000. The quantity of hemoglobin was always found to be consistent with the condition of general health of the patient. The length of the attack varies, as I believe depending upon the method of treatment employed; in two of the cases that had been treated for pulmonary tuberculosis the cough persisted for over three months; with proper treatment, begun at the proper time, the average duration commonly will not exceed two weeks.

Variations from this normal form are found in two directions; the rudimentary and the excessively developed forms. The rudimentary form is marked by incomplete development, in that the disease runs a shorter course; the temperature is not typical for a great length of time; the spasmodic cough is not thoroughly developed, and expectoration is limited.

The excessively developed form takes upon itself the clinical manifestations of an attack of septicemia, the cryptogenetic septico-pyemia of German authors (Leube); a large number of those cases called influenza-typhoid belong to this class. Again, here there are two forms, the mild and the severe. Of the first class eight were observed. This form is marked by the characteristic onset of the normal form; but either in the beginning or later stages elevations of temperature are noted that are much higher than in the normal form (103°-105° F.); the course of the fever being either intermittent, with subnormal or normal temperature in the morning, or remittent, usually accompanied by a rapid pulse. Sweats are not uncommon, but seem to bear very little relation to the height of the temperature. Chilliness exists, but distinct chills are rare. With high fever the expectoration is reduced and the spasmodic nature of the cough may disappear, at least the number of violent coughing spells is reduced. Depending upon the degree of intensity of the attack, there may or may not be moderate leucocytosis.

In none of the cases did we find the plasmodium malariæ, and in cases that were kept in bed the Widal reaction was always absent. The effect upon the general health is most marked. One of my patients, a physician, had his primary attack of influenza, of the respiratory form, in January, 1898; he recovered from this and continued his work. In April, 1898, he had a second attack which was accompanied and followed by moderate fever, occasional sweats and the characteristic cough. When he came under my treatment the beginning of June, he had lost, in all, forty pounds, he was extremely weak, emaciated and anemic, and all the symptoms still persisted as violently as they had in the beginning. He was sent to me with the diagnosis of phthisis pulmonalis. Examination revealed a weak right apex (slight dulness, diminished respiration, slight increase in vocal fremitus), a general bronchitis of the middle-sized tubes, profuse expectoration with streptococci and no tubercle bacilli. Since the middle of July, 1898, he has been perfectly well, has regained all his flesh, is in full practice, and has recovered completely from his tuberculophobia.

In the cases included in the epidemics referred to I have met with no other evidences of septicemia except those already mentioned. That this form is not uncommon is shown by the fact that out of 54 cases 8 suffered from it. The duration of the attack varies from weeks to months and in the latter case serious general disturbance may be set up.

Of the severe form there are two cases. The

first, a young man of twenty-three, who had a severe attack of influenza of the respiratory form accompanied by unusually high fever; after recovering from this the ordinary symptoms of streptococcus bronchitis appeared, but in ten days there developed a remittent fever whose evening maximum was 105° F. This continued for six days and then there developed a train of symptoms as follows: Irregular temperature with high maxima (106°-107° F.); great debility; very rapid pulse (110-160); tachypnea (50-60 respirations per minute); profuse sweats; hemorrhages into the skin; amaurosis (due to retinal hemorrhages); albuminuria; slight enlargement of the spleen; diarrhea; delirium; and, finally, after three weeks, death. In the lungs there were noticed no evidences of consolidation, but those of a general bronchitis; in addition there was the fact that during the latter ten days of the illness fibrinous casts of the larger bronchial tubes were expectorated. Examination of the expectoration revealed almost pure cultures of streptococci, and the membranes were those of streptococcus croup. No autopsy.

The second case was that of a physician, forty-seven years of age, who had had his primary attack in November, 1897, followed by streptococcus bronchitis, and who came to me on January 3, 1898, in the following condition: General bronchitis, recent endocarditis (mitral insufficiency); tachypnea; diarrhea; irregular fever, no chills; albuminuria; pains in joints; copious sweats; great debility. Streptococci and staphylococci were found in the expectoration; leucocytosis, 18,000. On January 4, 1898, streptococcus serum was injected, followed by very little improvement, due probably to the fact that the patient had been sent home and his physician did not understand the dosage of the serum. On the 17th of January the normal dose was administered and was followed by a marked improvement. It was again repeated on the 22d of January, and the report came that the patient was practically well; no temperature, the cough gone and respiration normal. On February 3, 1898, I received word that the symptoms had returned, and that the patient was suffering severely from dyspnea. Two days afterward I went to see him, and found a recent pericarditis and pulmonary infarct, from which he died in two days. Again no autopsy.

These two cases, presenting as they do the clinical pictures of septico-pyemia of bronchial origin, are the only ones I have seen in private practice. In hospital practice they are more common. They are representative of that which can be done by the streptococcus after influenza; but, under all circumstances, mild as well as severe forms must be looked upon as a septicemia, or septico-pyemia, the origin of the infection being found in the bronchial tubes. It may be proper to state that in the present epidemics we have had many secondary localizations of the streptococcus; in the intestinal canal, in the joints, in the kidneys, especially in connection with streptococcus bronchitis.

The complications that were observed were not many. Pneumonias are not so common with us as they are in other parts of the country, so that there were but three cases of pneumonia, in two of which the expectoration contained diplococci, streptococci and staphylococci; and in the third these bacteria plus the Friedländer pneumococci. In only one case could I satisfy myself that tuberculosis was either a complication or a sequela. This patient had an attack of streptococcus bronchitis in the winter of 1898, which was followed by the appearance of tubercle bacilli after two months. As a result of outdoor treatment she was restored to her normal condition—evidences of a slight infiltration in the left apex, and a compensated mitral insufficiency. In the winter of 1899 she had another attack of influenza, followed by streptococcus bronchitis, but no tuberculosis.

In patients whose cardiac condition was so evenly balanced that myocardial insufficiency could easily be produced, this developed, unless especial preventive measures were taken.

In the protracted cases, the differential diagnosis must lie between this secondary infection and that of tuberculosis of the lungs. It has been stated, I believe a little too rashly, that any patient who has for any great length of time subnormal temperature in the morning with slight increase in the evening, must be looked upon as suffering from phthisis pulmonalis. As a matter of fact, among all the cases observed—and it is for this reason that I have reserved only those cases which have been under observation for at least one year after the attack has run its course—I found only three cases that had tuberculosis, one already having been mentioned. In the other two cases tuberculosis developed, in the one, two years after the attack, and therefore, probably not to be looked upon as a sequela; and, in the other case, eighteen months after the primary attack.

The combination of streptococcus bronchitis with a weak apex of the lung is not an uncommon one and calls for great caution in differential diagnosis. On the other hand, it should be remembered that it is rare to find any human being with both apices alike; and, even if we were to call all those patients who had weak apices tuberculous, or as having latent tuberculosis, we would have to include a large number of human beings who never have shown or will show any other evidences of tuberculosis. Of the cases reported as becoming tuberculous none had hemoptysis nor bloody expectoration. On the other hand, those patients who had tuberculosis did not have hemoptysis.

The lines of differentiation must be drawn as to the general symptoms, the local symptoms, and, finally, the expectoration. While tuberculosis does develop after influenza, yet, if we find a combination of general symptoms with local symptoms, as I have attempted to describe them, there can be but very little difficulty in differentiation in the majority of instances. The objective signs on the part of the chest are those

of a general bronchitis, and not of a localization in one place or in another. If to these be added the fact that expectoration is profuse, and that repeated examinations fail to reveal tubercle bacilli, but always some other form of lower life, there ought not to be any hesitation in ascribing the proper cause to the symptoms.

It is possible that together with the signs on the part of the chest, as they have been described, there may be associated at the same time a tuberculosis; but under these circumstances the examination of the expectoration will always reveal the presence of the tubercle bacillus.

The treatment which I have pursued in these cases is as follows: In an attack of respiratory influenza I have made it a point to give quinine, my experience agreeing with that of some of the French observers that quinine has the peculiar property of preventing secondary infections. When streptococcus bronchitis develops I have used a remedy which I owe to my friend, Professor Glasgow of St. Louis, the benzoate of soda. This is to be given in large doses, one gram every two to four hours, always every two hours in the beginning. When the cough becomes too annoying, antipyrin, or codeine must be given; the codeine especially to prevent the dilatation that occurs so easily in hearts not perfectly strong. When the expectoration is too profuse, atropine or belladonna may be used to great advantage. In the severer forms, the unguentum Credé has been very serviceable; this combined with injections of antistreptococcic serum in the severest forms has in several instances given me good results. A change of climate seems to be of no benefit; indeed, some of the worst cases I have seen have come to me from health resorts.

Under all circumstances, we must not lose sight of the fact that we are dealing, first, with a local infection, and, secondly, with a general infection. The concept of a septicemia, acute or chronic, as the case may be, is the one that must guide us in the therapy to be employed.

FOURTH-OF-JULY TETANUS.[1]

BY H. GIDEON WELLS, M.D.,
OF CHICAGO, ILL.

In the twenty days from June 25 to July 14, 1900, there were reported to the coroner of Cook County twenty-nine deaths due to tetanus. During a similar period in 1899 there were seventeen deaths from the same cause. Of the twenty-nine cases during the last epidemic all but two are to be attributed to wounds from explosives used in demonstrating that Independence Day had come, or was coming, for the Chicago youth distributes his abundant patriotism over several days or weeks.

The twenty-seven victims were all boys, ranging from ten to seventeen years in age, and with one exception had received injuries from the discharge of blank cartridges. The exception was a wound from a toy cannon. As a general thing the wound was in the hand (24 of 27 cases, one each of the foot, eye and thigh), being received oftenest while the boy was trying to correct some error in the revolving or cocking mechanisms. The injuries were not due to bursting or any intrinsic fault of the weapons, but to the carelessness or inexperience of the users.

The period of incubation varied from five to nine days, and death occurred in from six to eleven days after the wound was received. None of the cases was of long duration, and in at least four it was under twenty-four hours. In other words the infection was of a virulent type, considering that as a rule the prognosis is much better when the period of incubation exceeds nine days, and recovery rare if shorter than this period. How many cases occurred in the city with a favorable outcome I do not know, but having heard of but a single case, despite diligent inquiry it is probable that they were few.

Why should tetanus be such a frequent result of Fourth-of-July wounds? It is of course impossible to tell how many boys were injured at this time, but these twenty-eight cases must represent a very large percentage; certainly a much greater proportion than results from the simple wounds received from other accidents. The fact that twenty-seven of the twenty-eight cases resulted from blank cartridges naturally suggests that tetanus bacilli might be present in the blank cartridges themselves, possibly from the use of dirty straw, etc., in the manufacture of the cardboard used for wadding. In seeking the cause of the epidemic of 1899 this source occurred to me, and I examined bacteriologically some two hundred blank cartridges, representing all the makes on the market. This research was reported in the *Philadelphia Medical Journal*, June 16, 1900. Despite all methods and modifications of technic tetanus bacilli could never be found in either wads or powder. Last year ten wads from each of the five makes in use were examined after the methods followed the preceding year, and the results were again negative. These bacteriological investigations, therefore, eliminate the blank cartridges themselves as the direct source of the infecting bacteria. It will be observed, as corroborating these results, that one of the fatal wounds was from a toy cannon, and also that during the twenty days in which the cases occurred there were two deaths from wounds not due to explosives. One was in a boy who fell from a tree and injured his hand; the other was similarly due to a wound of the hand with entrance of dirt and slivers of wood.

The remaining possible source of the tetanus bacilli, therefore, is the dirt which is on the hands, and which the blank cartridge wad carries in with it. Tetanus is endemic in Chicago, although not frequent; from one to four fatalities are usually reported to the coroner's office each month. These cases are oftenest due to the dreaded nail-

[1] Read before the Chicago Medical Society.

wound of the foot, although frequently they are from lacerated wounds of the hands or other parts of the body. The bacilli in these cases are unquestionably introduced with the dirt carried in by the wounding object. In order to verify this theory as to the source, specimens of dirt were taken from the street in six different parts of Chicago, and examined. They were exposed to heat, 85° C. for thirty minutes, and then inoculated into guinea pigs and culture media. One of the pigs died after about sixty hours, with typical manifestations of tetanus, and the tetanus bacillus was obtained from cultures made from the site of the inoculation. The cultures made from the same specimen of dirt as caused the tetanus contained an organism identical in morphology and staining with the tetanus bacillus, but on account of the presence of other resistant spored organisms it could not be isolated.

Why should tetanus occur so much oftener after these wounds than after ordinary lacerations? My own ideas cannot be better expressed than by quoting from an editorial in *Medicine* of August, 1900, which, referring to my previous article on tetanus, says: "The blank cartridge in exploding almost invariably wounds the hands; portions of wadding are carried beneath the palmar fascia, and the difficulty of drainage in puncture wounds of the hands and feet is well understood. When the average patriot goes out to celebrate the 4th of July, he usually betakes himself to some vacant lot or the streets of his native town, and after a few hours of energetic celebration his hands are covered with several layers of dirt. An explosion of a blank cartridge carrying the wadding beneath the skin is almost certain to take the tetanus bacillus with it, as street dirt and stable manure are the special habitats of this bacillus. An absence of early cleansing of the wound which is perhaps trifling and does not reach a surgeon, gives ample time and opportunity for this anaërobic germ to develop, with early general infection of the entire system."

Everything about the blank cartridge wound favors multiplication of the tetanus bacilli. It is long and narrow so that air cannot reach them. Aerobic organisms are present to exhaust any oxygen that may have entered. Blood clots and blood-saturated tissues are always present and they also favor the bacilli, for Strick[1] has shown that one one-thousandth the ordinary fatal dose of tetanus bacilli will kill a rabbit if injected into a hematoma.

The root of the evil of course lies in our barbaric method of celebration. That this can be changed is hardly to be hoped, at least in the present day and generation, and legislation for that purpose is not the special province of the physician. But after the boy has mutilated himself then the matter *is* in the hands of the physician, and with our present knowledge of the etiology and treatment of this disease we have the right to enquire if there should be any cases of tetanus from these injuries. The writer of the editorial quoted endeavors to leave a loophole for escape, by suggesting that the wounds are generally so trifling that they are not seen by a surgeon. He evidently considers that any surgeon would appreciate the gravity of the situation and take proper means to prevent the simple wound becoming the source of a fatal complication. Unfortunately this is not so. The boys who died in Chicago last summer *were* seen by physicians. In studying this epidemic a list of questions was sent to the parents of these children and answers received from the majority. Nearly all stated that the wound had been seen by a doctor shortly after it was received.

Leaving out the question of tetanus and considering alone the matter of sepsis, is any physician justified in leaving pasteboard wads shot into a grimy hand, at the bottom of a contused and lacerated puncture-wound? Yet this is the condition that was present in nearly every case of tetanus that followed these wounds. This applies by no means to Chicago alone, for the reports of cases and dispensary statistics from the country at large tell the same story of the finding of wads at the bottom of the wounds by the surgeon who was called in after tetanus had developed. Considering the infrequency with which tetanus follows wounds that are well cleaned and drained, it seems as if some of these fatalities, if not all, would have been prevented by ordinary surgical methods.

Occasionally, however, tetanus results from wounds that have received the best of care, developing sometimes after complete healing has occurred and all danger seems past. These cases are ordinarily not preventable, for tetanus is such a rare complication that few surgeons would consider it necessary to take any specific precautions against it as a routine practice. But knowing the frequency with which blank cartridge wounds cause tetanus, should not tetanus antitoxin be used as a prophylactic in all such cases? Tetanus antitoxin has not been used as a prophylactic in man to any extent, for the reason just given—that tetanus is not an expected complication. As a curative agent it has not given curative results, such as has diphtheria antitoxin, presumably for the reason that it is not administered until the patient is practically in the last agonies, it being understood that the trismus and spasms, which are usually the first indications, do not ordinarily occur until the fifth to the twelfth day of the disease. But as a prophylactic its action is positive, according to the veterinarians who use it extensively. They have many chances to observe its effects in stables where tetanus becomes endemic. In such a stable on the west side there had been for several years from six to eight deaths from tetanus annually. It was decided to give every horse with wounds about the feet a prophylactic dose of antitoxin. During the five years since this plan was adopted about three hundred horses were so treated, and none developed tetanus. One horse only with wounds was not injected during this time and it de-

[1] Centr. f. Bakt., Bd. xxv, s. 386.

veloped tetanus, the only case occurring during the five years. Many similar series are reported by veterinarians. It is also interesting to note that as a curative agent antitoxin has given no better results in horses than in man, hence it is reasonable to suppose that it would be fully as successful as a prophylactic for man as for the horse. The usual prophylactic dose for a horse is ten cubic centimeters, so half that amount would probably be a great sufficiency for a man, and if we can compare it with diphtheria antitoxin this prophylactic use would be free from danger. As a matter of fact it has been used sufficiently as a prophylactic already to show that its use is quite safe.

To summarize the facts and impressions of this paper it may be stated that: Tetanus is endemic in Chicago, the specific organism being present in the dirt of the streets. Every Fourth of July an epidemic occurs, because these bacilli are carried deeply into wounds before wads from blank cartridges, and are then under favorable conditions for multiplication. Epidemics which always occur in other portions of the country at the same time are presumably due to the same causes. Most of the cases occur in wounds that have been improperly cared for, the wads not having been removed or suitable drainage instituted. Therefore the first indication is to secure thorough surgical cleansing and drainage of the wound, preferably and almost necessarily under an anesthetic. As, however, tetanus sometimes occurs even in well-drained wounds, and considering the frequency with which it follows blank cartridge wounds, it seems to the writer that such cases should receive a prophylactic dose of, say, five cubic centimeters, of tetanus antitoxin, as soon as possible after the wound is first seen. It seems certain that if antitoxin prophylaxis were adopted there would be no further Fourth of July epidemics, and this end justifies the means.

Pathological Laboratory, Rush Medical College.

THE USE OF METHYLENE-BLUE INJECTIONS IN PLEURISY WITH EFFUSION.[1]

BY CHARLES H. LEWIS, M.D.,
OF NEW YORK.

I have been requested by the President to give a résumé of the method which I employ in treating some cases of pleurisy with effusion.

My early experiences with this method were incorporated in a paper on "The Treatment of Serous Effusions" read at the Hospital Graduates' Club, something over a year ago, and published in the *Medical Record*, December 30, 1899.

I regret that I have little especially new to add and but four new cases to append to the series published at that time. This is not, however, extraordinary when I recall that it took me over three years to gather and study the twenty cases reported in the article alluded to. I must also confess to a discontinuation of the practice I had previously indulged in of borrowing from my colleague's wards every case of plural effusion that I could lay my hands on. To lessen the responsibility of letting loose a new therapeutic measure on a long-suffering, medical community, and to purge myself of the charge of rank empiricism, it may not be out of place on this occasion to suggest some of the considerations which led me to employ methylene blue in the treatment of serous effusions.

The rationale of the absorptions of pleural effusions has always possessed an especial interest to me, as it seems it must to every one who sees and follows the course of many of these cases. Why it is that the lymphatic sponge soaks up the fluid in the pleural sac in such an irregular—almost erratic—fashion, uninfluenced frequently by diminished intake and increased output of liquids, is, and always has been, quite incomprehensible to me. It is not an infrequent experience to observe fluid remaining unchanged in a pleural cavity for weeks and months, all of which time the patient is undergoing a rigorous and enervating course of cathartics, diuretics, and diaphoretics, and then note its abrupt recession and comparatively rapid disappearance. In other cases the serum is taken up by the lymphatics promptly and energetically under eliminative, salicylic, iodide, counter-irritative, or no special treatment. The pleural surfaces meet and are firmly and permanently glued together. The patient recovers with thickened and adherent pleural walls. No further encroachment of serum is to be apprehended, and with the exception of a possible subsequent slight contraction, the chest is to all intents and purposes normal. According to Dr. Frank Ferguson, autopsies on 80 per cent. of the cases dying of other than chest disease exhibit more or less general pleural adhesions. Samuel Gee in "Allbutt's System of Medicine" states that "recovery from pleurisy carries the assumption that adhesion has occurred." Osler, in his last book, remarks that "adhesions are probably an invariable result whether the pleurisy is primary or secondary." "Indeed," he adds, "it is rare to examine a body entirely free from them." And again, "they may exist without giving rise to the slightest disturbance in the function of the lungs."

In emptying a pleural cavity of fluid, two methods may be employed. First, aspiration, and, second, absorption through the lymphatic channels. So far as rapidity is concerned, aspiration as recommended by Bowditch forty years ago, furnishes an ideal method. With modern asepsis and average care the operation is entirely free from danger. The objection is the often rapid re appearance of the fluid, and the consequent necessity of a frequent repetition of the operation. On the other hand, in my experience, spontaneous absorption by the lymphatic stream, when effective, leads to permanent results.

The therapeutic resources ordinarily recom-

[1] Read before the Section on Medicine, of the New York Academy of Medicine, Feb. 19, 1901.

mended for facilitating absorption are uncertain in their action, and debilitating in their effects. Diuretics and strong counterirritants have had their day; Osler "damns with faint praise" weak counterirritants by saying "in some cases they appear useful." Hydragogue cathartics drain fluid from the vessels, but carry no assurance that the latter will recoup themselves from the reservoir in the pleura; diaphoretics possess all the disadvantages of hydragogue cathartics with none of their advantages; iodides and salicylates serve as forlorn hopes; antiphlogistics are antiquated and unscientific; Notimagel pronounces "diuretics, cathartics and diaphoretics not only useless but harmful."

In studying the course of pleural effusions it occurred to me that if we could introduce some substance into the pleural cavity which would secure a more or less general deposit of fibrin on the pleural surfaces, and then aspirate, adhesion of the walls of the sac would result in sufficient quantity to prevent a return of the effusion; if the substance employed were antiseptic—since all pleural inflammatory effusions are pretty generally conceded to be due to microorganisms—an additional argument for its use could be adduced. Then, again, it might stimulate the absorbents.

Such were the considerations which induced me some four years ago to experiment with iodine, potassium permanganate, and the aniline dyes, fuchsin and methylene blue. After many observations, which it is unnecessary to detail here, but which are described at some length in the article already alluded to, I selected the blue as being easily the most likely to secure the contemplated results. Methylene blue is antiseptic, anodyne, has diuretic properties, is easily detected in the urine, and imparts a color not found in any bodily secretion, physiological or pathological. Delafield and Prudden have demonstrated that pleural adhesions can be evolved by irritant injection into the pleural sac after the preliminary stages of congestion and fibrinous deposit. They have also established the fact that the character of the exudation varies directly with the strength of the irritant. In order to safely throw a feebly irritating solution into a serous effusion so that the former may come in contact with the entire surface which the serum bathes, certain conditions must be fulfilled: (1) The irritating material must form an easy and permanent solution in the vehicle employed and in the serum; (2) the reaction and specific gravity of both fluids must correspond as closely as possible; (3) the material injected must be antiseptic or easily rendered aseptic, and (4) the volume of the fluid in the sac must remain unchanged.

After a not altogether satisfactory test of a saline solution approximating to the specific gravity of the serum as a vehicle to carry in the methylene blue, the idea occurred to me, to use the serum itself as a solvent, and, after making a solution of it and the blue, to return both into the cavity. By such a procedure every essential would be fulfilled. As I had already determined, serum readily dissolves methylene blue in about 1 to 50 parts. The reaction and specific gravity would obviously agree, being a part of the whole. If no infection occurred during the trip its condition as to sterility would be as good as before—which is not always the best—and, finally, the amount borrowed would be paid in full so that no change in volume would result. It was expected that the respiratory movements and the operation of injection would produce sufficient agitation in the chest cavity to make a uniform mixture of the two serums. This expectation was fully realized as subsequent hypodermic taps at different points over the affected chest gave a fluid of uniform color and appearance. This easy and uniform miscibility of a solution of methylene blue and serum has been utilized by Niclot in estimating the total amount of a pleural effusion by the color of the sample withdrawn after injection of the dye. In *La Semaine Médicale* of November 28, 1900, he cites three cases in which the amount of fluid was accurately determined by such colorimetric observations.

The method which I formerly employed for withdrawing the fluid, making the solution, and re-injecting into the serous cavity, is practised by means of the large aspirating-syringe with a needle of medium caliber and fitted with asbestos piston and washers. A rubber tube is attached to the outflow tube of the syringe and extends into a glass graduate of a capacity of 100 c.c. or more, which holds the methylene blue. A glass rod for mixing the blue and serum is inserted into the vessel alongside the rubber tube and the entrance is then plugged with sterilized cotton. The whole outfit before use is easily sterilized by heat. If the sterilization is thorough, infection of the serum on the round trip from sac to vessel and return is impossible. Ordinary care renders the needle clean. The methylene blue being put into the graduate before sterilization is itself sterilized. It is, however, antiseptic, and I have never been able to get any growth from it in culture media even when coming from sources which would contaminate non-antiseptic materials. I have recently varied this method by applying the principle of the Potain aspirator, carrying the tube which withdraws the serum to the bottom of the vessel. The short tube through which the air is exhausted remains as usual. Any aspirating-syringe will serve. The serum can then be drawn into the graduate by the ordinary method, readily mixed by agitation with the blue which has previously been placed therein, and then forced back into the pleura by reversing the action of the aspirating-syringe. The process can be repeated a sufficient number of times to take up all, or nearly all the blue. This method does away with sterilizing the syringe, and otherwise preserves it (for the action of the blue is rather destructive to the valves); it also shortens the course over which

the serum travels and lessens proportionately the liability to possible infection.

I have employed this method of treatment in 24 cases of pleural effusion including one suppurative case. In this case fifteen grains of methylene blue was injected at Columbus Hospital, May 11, 1900, by the same method that I have described for the serous cases. The dye was found in the urine four hours later, and was excreted sluggishly but continuously until the pleural cavity was emptied by free incision May 22d, after which date the greenish tint gradually faded from the urine. The fluid evacuated measured about three quarts of bluish-green pus of rather offensive odor. Subsequent adhesions formed rapidly, and the patient left the hospital June 12, 1900—thirty-two days after injection and twenty-one days after operation with a small discharging sinus which healed uninterruptedly under dispensary treatment. Castaigne in *La Presse Médicale*, March, 28, 1900, concludes, after considerable experimental work in this direction, that there is no absorption of soluble substances in a pleural suppurative effusion due to tuberculous or pneumococcus infection. He readily admits, however, this absorptive power to the pleura in empyemata of streptococcus etiology and even in a hemorrhagic effusion of cancerous origin.

Of the 23 serofibrinous cases treated by this method, short histories of twenty appear in my original article. The course of the three additional cases deviated in no essential particular from the first series. One, however, accompanied by well-marked signs of pulmonary tuberculosis, and presenting abundant tubercle bacilli in the sputum, exhibited an unusually tardy elimination of the blue in the urine, namely, fourteen days. The pulmonary complications of this patient delayed his convalescence and he remained twenty-six days in the hospital after the injection. After a month's subsequent treatment in the dispensary he still had his cough and a mild fever, but his general condition was fair and with the exception of some dulness and a few crackling râles no evidence of his plural trouble presented. The average duration of treatment for the 23 serofibrinous cases was a little under fourteen days (13.8 days).

In this list, besides the injections of methylene blue as described, some cases received salicylates, some diuretics or cathartics, and others no internal medication at all. So far as I could determine, drugs used internally had little or no influence on the rapidity of absorption. "Wolff bottles," as recommended by Dr. Walter B. James for facilitating lung distention, were employed in all cases, and with good effect. The shortest interval between the injection of methylene blue and its appearance in the urine was one hour.

Raymond and Tourlet (*La Presse Médicale*, March 14, 1900), after injecting 10 cg. (1½ grains) of methylene blue into a pleural serous effusion found the blue in the urine drawn by catheter one-half hour later. In four of my cases paracentesis was performed a few days after injection without cutting short the period of convalescence. No considerable re-accumulation of fluid could be made out in these cases, but absorption of the rest of the effusion—for it is impossible, even if advisable, to completely empty the chest cavity—dragged along at a snail's pace, so that the time from injection to discharge from the hospital was something more than two days over the non-aspirated cases.

The quantity of methylene blue employed was from 5 to 15 grains. Most of the cases received over 10 grains. The amount of serum, by the first method, was 60 to 100 c.c. By the second, no estimate was made, but sufficient employed to carry in the dye. In this connection it is interesting to note, by way of corroboration, that Renon (in the *Bull. de l'Acad. Méd. de Paris*, July 31, 1900), reports two cases where the blue was introduced into the pleural cavity in conditions of serofibrinous exudation. In one case, the elimination, by way of the urine, lasted *nine* days; and in the other, *three* days; and he adds, "the rate of elimination corresponded with the rate of absorption of the fluid."

47 West Fifty-eighth Street.

THE APPEARANCE OF THE SOFT PALATE A PATHOGNOMONIC SYMPTOM OF EPIDEMIC INFLUENZA.

BY LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C.

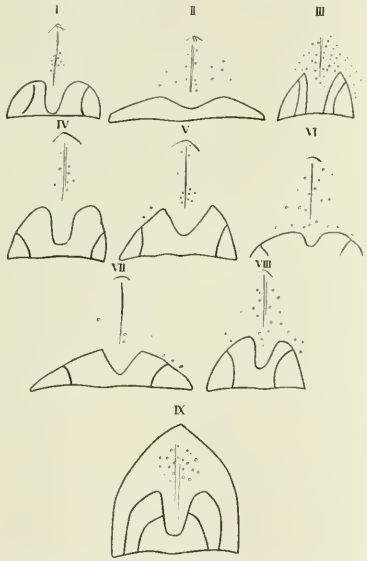
From a habit of examining the fauces in all cases of epidemic influenza that presented themselves and from the same practice in all instances in which the disease was suspected as the primary cause of sickness there has grown gradually the conviction in the writer's mind that influenza can be diagnosed with ease and certainty by observing the peculiarity of appearance of the *velum palati*. This was found to be constant where the general symptoms were sufficient to make a diagnosis certain. It was further noted that it preceded the initial chill and fever by some days and that it still persisted when convalescence was apparently ended.

Of greater utility and satisfaction, perhaps, was that its presence made clear the origin of those numerous anomalous types one sees during an epidemic of grip in which its recognition is neglected or the causal factor is suspected after such an irregular case has run its more or less protracted course. Thus, acute eczema, bilious vomiting, morning vertigo in women, irritative laryngeal cough, neuralgia of the face and chest, acute pelvic pain in women are some of these irregular forms.

The phenomenon in question is seen upon the mucous membrane of the soft palate in the form of small convex projections of a pearly whiteness or transparency. Their size is that of a grain of sand. In number they are either few

and confined to certain parts of the velum or its processes, or else abundantly scattered over the whole of its anterior surface. The certain parts exquisitely displaying them in their circumscribed form are, (1) the base of the uvula; (2) the median raphe; (3) the lateral borders of the same; (4) the anterior surface of the palatoglossal fold about the upper border of the tonsil. A spatula rubbed over them give a hard, rough sensation.

They are not distinguishable in obscure light, as in cloudy weather, nor discernible in any but a very bright artificial illumination and are best seen in sunlight, direct or diffused. They must not be confounded with minute drops of mucus or saliva often present. Sometimes they are entirely obscured by a tenacious secretion covering the surface. The use of a handkerchief or the handle of a spoon to remove this gives the peculiar rough feel and reveals the little projections on the mucous membrane. It it assumed that their composition is that of congested or inflamed palatal mucous glands. I have had no opportunity to study their pathologic histology.



Diagrams of Soft Palate in Epidemic Influenza.

The color of the field to these bodies is flesh red in the otherwise normal individual; angry red from the consumption of alcohol or smoking tobacco; waxy white in the tuberculous, and in those subject to other wasting diseases. Sometimes punctate hemorrhages complicate the picture, and in a single instance the color of the little enlargements was bright red.

Their existence is devoid of any subjective sensation. I have never observed a patient conscious of their presence, however morbidly alert he may have been in discovering and enlarging upon his feelings in sickness.

The accompanying diagrams were sketches from patients: (I.) A boy of seven; acute laryngitis; second day of influenza. (II.) Female aged forty; uvula and tonsils removed some years ago; seventh day; (III.) Male of sixty-five; chronic alcoholism; surface deep red; fourth day; (IV.) Female, twenty-four; anemic, tenth day. (V.) Male, twenty-six, sixth day. (VI.) Female, thirty-three; third day. (VII.) Female, sixty-six, second day. (VIII.) Child, four years, third day. (IX.) Female, twenty, first day.

MEDICAL PROGRESS.

Membranous Enteritis.—In his studies on membranous enteritis, H. Westphalen (*Berl. klin. Woch.*, Apr. 22, 1901) concludes as follows: (1) that the disease cannot well be subdivided into a membranous enteritis depending on a catarrh and a mucous colitis, an intestinal neurosis; (2) that the formation of the so-called enteric membranes depends on a purely nervous hypersecretion of mucous; (3) that if there is an uncomplicated neurosis large masses of amorphous mucus are passed; (4) that if spastic intestinal conditions are added, the mucus is compressed in the form of stringy masses; (5) and lastly, that if the masses are voided with severe pains, one is justified in assuming an additional sensory neurosis.

Morphine and Chloroform.—Lauwers (*Jour. de. Chir.*, 1901, No. 3) states that after considerable observation of actual and threatened fatalities after chloroform anesthesia among patients to whom morphine was given hypodermatically directly after the operation, he has concluded that the bad results are more often due to the morphine depression than to the chloroform depression. He therefore believes that as a rule when chloroform has been the anesthetic, morphine should not be administered until several hours have elapsed. In the resuscitation of collapsed patients after chloroform narcosis he has found that irritation of the mucosa of the trachea is a most potent and certain excitant of the respiratory reflex. His attention to it was called by the violence of the response when during tracheotomy the mucosa is stimulated with gauze for removing false membranes or mucous collections and also in the physiological laboratory by experiments on animals, when revival of the breathing was obtained even after all life was evidently gone.

Freezing Point of Blood.—The great diagnostic value of the freezing point of the blood is justly emphasized by A. Koranyi (*Berl. klin. Woch.*, Apr. 22, 1901) and the normal limits are given by him as being 0.56-0.58° C. Though some surgeons have reported absence of renal in-

sufficiency in cases where 0.60° C. was found, it must be remembered that both carbon dioxides and acetone in the blood will alter the freezing-point. It is therefore necessary to treat the blood freely with oxygen before freezing it or at least to shake it for some time. Another great source of error lies in the use of improper apparatus.

Uterine Congestion and Sclerosis.—L. G. Richelot and J. Barozzi (*La Gynecologie*, 1901, No. 1) emphasize the fact that in the treatment of these two conditions respect must always be had for the age of the patient and the degree of the conditions. With the young virgin rest in bed is the true basis of the management, which should be begun as soon as the diagnosis is made and continued until the symptoms have subsided. After the real congestion is absolutely cured, rest in bed during the entire menstrual period with both the preceding and following twenty-four hours is the best prophylactic measure against a recurrence of the trouble. Between the monthly flows attention should be intelligently given to hygienic living and the avoidance of excessive exercise like bicycling, horseback-riding, dancing, etc. In the severe cases the uterine tonics may be used, especially, hydrastis canadensis, viburnum prunifolium and piscidia erythrina. Quinine sulphate is always to be thought of as a most serviceable drug. If the patient be an older woman, then in addition to the above general principles we use the simple or medicated douche in large quantity several times daily and as hot as can be borne; hot rectal irrigation; vaginal and rectal suppositories directed against pain and congestion; vaginal glycerine tampons combined with ichthyol and other drugs. As a later resort comes the various intra-uterine applications, especially the milder caustics nitrate of silver and sulphate of copper, or later in the bad cases chloride of zinc under suitable precautions. Hydrotherapy, cold water in a few selected robust cases, hot water in the vast majority of patients, must never be forgotten. In the wealthy resort to some of the baths may be had in obstinate cases. A rational alimentary hygiene must never be forgotten. Simple highly nutritious diet and the total avoidance of all constipation must be the rule. In general alcoholic drinks, stimulating tonics, all ferruginous medication tend to increase the congestion and are usually contraindicated. Repeated congestions often go on to sclerosis of the uterus and then we have to consider its treatment. Divulsion of the cervix with tents is an excellent means of producing softening of the entire uterus, especially the cervix and is in these early cases better than forcible dilatation. Next in order comes a careful systematic curetting as a last resort if all other means, when repeated have failed, then hysterectomy *per vagnam* is to be considered.

Treatment of Pertussis.—Excellent results have been obtained in the treatment of whooping-cough by G. Seuss (*Münch. med. Woch.*, Apr. 9, 1901) by the use of orthoform locally applied to the larynx and glottis by means of a powder insufflator. The slight solubility of orthoform will allow its anesthetic properties to manifest themselves for hours so that a reflex contraction of the epiglottis will become impossible while after-effects can be seen only in those few patients who manifest an idiosyncrasy.

Bacteriological and Clinical Phenomena of the Puerperium.—G. Vogel (*Zeitschr. f. Geburtsh. u. Gynäk.*, B. 44, H. 3, 1901) draws the following conclusions: (1) The formation of a copious secretion is a condition which soon disappears without harm to the woman, provided it is cared for with the proper precautions; (2) in the great majority of cases when there is a rise of temperature during the puerperium pus can be found in the uterus; (3) in women who have a fever and a positive bacteriological diagnosis there is almost always some clinical abnormality in the parturient canal; (4) in such cases there is usually some source of retention of the discharge, as a rule consisting of a dextro- or sinistro-version easily curable; (5) when such retention is suspected contraction of the uterus must be brought about and always free evacuation of the pus and cleansing of the cavity with 20 per cent. carbolic acid in alcohol; (6) lacerations of the cervix encourage the advance of pus into the uterus and with that the fever and other symptoms; (7) small wounds of the genital tract favor the development of pus, therefore all such must be most carefully cleansed; (8) during the early puerperium in normal cases as a rule the uterus is absolutely free of pus, but nevertheless pus and even streptococci may be present without giving an evidence clinically of their existence; (9) during the late puerperium the uterine contents are still more apt to contain pus and still more rarely does such pus cause even the slightest disturbance; (10) streptococci are very rarely found in fact in women entirely free of fever.

Blood Transfusion.—A. Bier (*Münch. med. Woch.*, Apr. 9, 1901) has employed transfusions of lamb's blood in various forms of cachexia and tuberculosis with marked improvement. An intense reaction is caused throughout the entire body which is most marked in the diseased organ where the hyperemic will bring on healthy, reactive changes. Small quantities of the blood, which must first be defibrinated are injected into a vein in a manner similar to that used for cinnamic acid in tuberculosis.

Errors in Diagnosis of Appendicitis.—G. E. Brewer (*Annals of Surgery*, May, 1901) cites cases in which erroneous diagnoses of appendicitis were made clinically and the true condition ascertained later by operation or other means. Among the instructive cases epitomized are two of renal calculi which closely simulated the symptoms and signs either of appendicitis or biliary calculi. They were free from the classical symptoms of hematuria, vesical irritation and lumbar tenderness and were not palpable in the kidney when exposed by lumbar incision. Two cases of right ovarian and parovarian cysts strangulated by a

twist in the pedicle very closely simulated the appendical inflammation. In one patient a torsion in a hydrosalpinx was the true lesion. In another cholecystitis with obscure signs very closely simulated the appendicitis. One patient showed that a negative palpation of the pancreas through the stomach and the substance of the great omentum is by no means a proof that an acute suppurative pancreatitis does not exist, and that the existence of small areas of fat necrosis over the omentum and other viscera is a very good indication of the presence of such a lesion and that the general sepsis caused by the lesion may very deceptively imitate the symptoms produced by a general infection of the great peritoneal sac. A rapidly growing sarcoma of the small intestine may simulate an acute appendicitis, especially when it does not produce preliminary obstruction or other symptoms. Severe general sepsis although from foci entirely removed from the abdominal cavity, may produce symptoms very remarkably like those due to a local or general peritonitis.

Glutoid Capsules as an Aid to Diagnosis.—In the diagnosis of diseases of the intestines and also of the pancreas, capsules of iodide of potassium, where the gelatine had been treated with formalin have been recommended, since, while insoluble in gastric juice, they readily disintegrate in the small intestines. F. Fromme (*Münch. med. Woch.*, April 9, 1901) recapitulates as follows concerning their utility: (1) if the reaction occurs within the normal time (3½-5 hours) it proves a good gastric motility and normal pancreatic function; (2) if the reaction takes place later than 7-8 hours it is not conclusive, as it may signify pancreatic disturbance, yet the capsules may be held back in the stomach from various causes.

Streptococcus in Gynecology.—The most frequent puerperal infection is that of the streptococcus, which extends through the uterine walls particularly at the site of the placenta, and often sets up an anterior, posterior, or lateral parametritis. Generally these infections are limited to the pelvic lymphatics, but they may cause abscesses as high as the umbilicus anteriorly, the mediastinum posteriorly, or on the venter of either ilium. Guy L. Hunner (*Am. Gyn. and Obstet. Journ.*, May, 1901) considers that the probable diagnosis should be made from the history alone, palpation being of next importance. The dense cellulitic mass usually situated in the subperitoneal tissues, and localized on one side or in one region, he designates as the characteristic postpuerperal streptococcus lesion.

Artificial Respiration.—The abdominal method of artificial respiration introduced by T. E. Satterthwaite is described (*Post-Graduate*, May, 1901) by him as follows: To get rid of the water in the body, place on face with outstretched arms, and head lower than hips, wedge mouth open with a bit of wood or knotted handkerchief. Kneel at right of patient, and while depressing patient's tongue with right hand, push bowels and other abdominal viscera against diaphragm with left hand. Keep up pressure until water ceases to flow from mouth, or until artificial respiration can be made effective. Then turn body on back, in horizontal position, arms at sides, raise pit of stomach by a bundle of clothing under back, and with right finger on back of tongue press the diaphragm upward with left hand. Then cease pressure and the diaphragm will fall and the lungs inflate with air. Begin with three or four movements in a minute, and increase to ten or fifteen. If there are two operators, Sylvester's plan may be employed in addition. When respiration is re-established, remove to a warm place, apply dry heat to the body, and cautiously give hot broth, beef tea, or alcoholics, at first in minute quantities.

Relief of Nephroptosis.—Various methods have been devised by which it was supposed that a movable kidney could be held in place by the application of an abdominal binder. G. M. Edebohls (*Med. Rec.*, May 4, 1901) shows how difficult it is for one to prevent the descent of a movable kidney even by the clever application of the hand, and hence mechanical support could hardly be expected to be efficacious unless an unbearable pressure was exerted. Furthermore, manipulations or pressure upon the kidneys have been shown to materially change the character of the urine. Kidney pads, therefore, should never be used. Since simple bandages act by supporting the entire contents of the abdomen the degree of benefit will depend largely upon the amount of general enteroptosis which accompanies the nephroptosis. In all cases in which relief of the symptoms cannot be obtained from the simple bandage or corset, nephropexy is indicated.

Abdominal Pain in Typhoid.—Very little attention is paid by authors to this very frequent and distressing symptom. F. McCrae has analyzed 500 cases appearing in the Johns Hopkins Hospital (*N. Y. Med. Jour.*, May 4, 1901) and finds that pain is present at some time during the illness in at least two-fifths of the cases. Pain occurred with perforation or hemorrhage in about five per cent. of all cases, and it was most constantly present with perforation, when it was usually sudden in onset, sharp in character and paroxysmal. The pain of perforation was most closely simulated by the pain of hemorrhage, of phlebitis or of unknown origin. Among the other frequent causes of abdominal pain he mentions pleurisy, pneumonia, distended bladder, solid food, vomiting or constipation, appendicitis, peritonitis, cholecystitis or liver abscess. At the onset of the disease the pain may be so severe as to lead to a mistaken diagnosis and yet no adequate cause for the symptom be made out. In over twelve per cent. of patients complaining of pain no discoverable cause was detected and of these there was a considerable number who presented many of the features of perforation, such

as local abdominal symptoms and a moderate leucocytosis. Several of these when operated upon showed nothing but a slight peritoneal irritation at the site of a Peyer's patch.

Suprarenal Extract in Cardiac Disease.—The dried and powdered gland loosely packed in a gelatin capsule is thoroughly chewed and swallowed without water. About three grains is an ordinary dose and S. Floersheim (*N. Y. Med Jour.*, May 4, 1901) finds that when such a dose is properly administered, a decided effect upon the heart's action can be noted within five minutes, at which time the maximum effect is obtained. The action is continued from five minutes to three hours and the influence seems to be to increase the force of the heart beat and improve the tone of the vessels. There seems to be no contra-indications and poisonous effects are unknown.

Traumatic Rupture of Cardiac Valves.—The mooted question, whether rupture of a heart-valve may result from external violence, is answered in the affirmative by F. Strassmann (*Zeitschrft. f. klin. Med.*, Vol. 42, Nos. 5 and 6). This patient sustained a contusion of the chest and in the course of six months developed all the symptoms of disturbed circulation which ultimately led to his death. At autopsy healed fractures of four ribs, dilatation of the heart, pericarditis, partial rupture of the aorta and rupture of one of the aortic valves, together with the usual signs of decomposition were found.

Transudates and Exudates.—The usual rules that exudates have a specific gravity above 1018, albumin more than 5 per cent. and an acid reaction, while transudates are lighter than 1018, contain less than 5 per cent albumin and are alkaline, often do not suffice for a differential diagnosis between both. A. Wolff (*Zeitschrift f. klin. Med.*, Vol. 42, Nos. 5 and 6) recommends a study of the morphological elements. He recognizes two groups: (1) where there are polynuclear leucocytes with a few erythrocytes; (2) where lymphocytes and erythrocytes form the main elements. The former corresponds to the exudates, the latter to the transudates. In tuberculosis the elements found generally belong to the second group; this, together with the usual sterility of the fluid, stamps it as a transudate caused probably by irritation of the pleura by the toxins of the tubercle bacillus. If a cavity breaks into the pleura, the transudate morphologically becomes an exudate.

THERAPEUTIC HINTS.

Middle-Ear Diseases.—If the Eustachian tube is closed by inflammatory products, inflation should be performed, or, if this fails to open the tube, the Eustachian catheter may be passed. The nasal cavity should always be cleaned before the inflation, or septic material may be carried up the tube. After inflation, the pharyngeal end of the tube should be treated with astringents. In acute otitis media, put the patient to bed, give saline cathartic, and apply dry heat to relieve the pain. Avoid moist heat, oils, and aqueous solutions. Leeches may be applied in front of the tragus. If the pain is very severe, coal-tar products may be given, but avoid opium as it may mask the symptoms of a mastoid involvement. If these measures do not relieve early, open the drum; if it perforates make the opening large enough for free drainage. Pay special attention to the condition of the nose and pharynx. The chronic hypertrophic or hyperplastic inflammations causing dull hearing and subjective noises are most frequently caused by adenoids, enlarged pharyngeal tonsils, hypertrophied turbinate, or deflected septum. If still in the hypertrophic stage and there is fluid in the middle ear, inflate to remove it by the Eustachian tube; or, if this fails, do paracentesis and then inflate with absorbing and stimulating vapors, making mild massage of the drum. If the middle ear is in a hyperplastic condition with atrophy, it is best to remove the malleus and incus and mobilize the stapes. Remember that middle-ear disease of one side tends to the impairment of hearing on the opposite side.—E. V. Riker (*The Physician and Surgeon*, April, 1901).

Camphorated Oil.—Camphor is an antispasmodic and a powerful cardiac tonic, capable of restoring the vigor of the heart-muscle when it is weakened by pyrexia. It is not toxic, but one gram (gr. xv) a day is full dosage. The only contraindication is pregnancy, as abortion has resulted from large doses. Given by injection, camphorated oil acts rapidly, is painless, and does not produce nervous symptoms like caffeine. In tuberculosis it modifies the bronchial secretions and stimulates phagocytosis. The mean dose for an adult should be 2 to 8 grams (℥ss-ij) a day of 10 per cent. oil.—E. Vaillant, *Journ. de Méd. de Paris*, Apr. 28, 1901.

Salol in Diabetes.—Of eight cases treated by M. Tesmacher, three received no benefit. The other five had a fairly intense diabetes, with persistence of 0.6-1.5 per cent. of sugar in the urine in spite of antidiabetic diet. After about five days administration of salol gm. 1.3 (gr. xx) three times a day, the urine contained only traces of sugar. When the salol was stopped, the sugar gradually reappeared.—*La Presse Méd.*, Apr. 24, 1901.

Eczema.—Ehrmann employs:

℞ Petrosulfol .....gm. 6.0 (℥iss).
Caseine ointment..gm. 20.0-40.0 (℥v-x).

or

℞ Petrosulfol .....gm. 6.0 (℥iss).
Lanolin
Vaselin aa..... 20.0 (℥v).
Zinc. oxid..... 10.0 (℥iisss).

Journ. de Med. de Paris, Apr. 28, 1901.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE ANTEPARTUM BATH.

THE events of labor and the puerperium are essentially physiological and should therefore normally be exempt from pathological manifestations, yet the proportion of cases in which the postpartum temperature exceeds the bounds of health is very considerable. Statistics of European maternities give as the lowest figure 17 per cent. of postpartum temperatures while many authorities consider a rise to 101-101.8° F. normal for the child bed. Modern methods, particularly the universal adoption of aseptic and antiseptic measures have greatly reduced the proportion of puerperal casualties but the percentage of postpartum fevers is still so great as to indicate that even our best efforts are open to criticism and that we are still leaving loop holes for the entrance of disturbing factors.

By most writers these faulty results are attributed either to the introduction of septic matter into the genitalia in the process of internal examination and irrigation or to autoinfection; and to reduce these risks the use of gloves, the restriction of vaginal examinations, careful disinfection of the vaginal tract during the labor and also the total omission of such cleansing efforts have all been recommended, while it has also been shown that the vagina itself has definite bactericidal self-purifying powers. But in spite of precautions there is still a wide gap to be bridged before the ideal can be approached and several writers have lately been considering the antepartum bath as a possible fallacy.

The ordinary tub bath is open to a number of objections since the patient at the end of the scrubbing is virtually immersed in a dilution of her own dirt. That which is removed from the more contaminated regions such as the feet, hands and anus, particularly the latter if, as is the case, the routine enema immediately precedes the bath, is spread in a thin film over the whole body while if any ulcers or discharging wounds are present a distribution of infectious organisms over the entire surface inevitably takes place. There are probably not many institutions where an adequate disinfection of the tub before use is carried out so that each bather is likely to receive contributions from the person of her predecessor and altogether the procedure is far from being a satisfactory cleaning process. Furthermore it is more than probable that in the movements of entering and leaving the tub, respiration, etc., some of this infected water enters the vagina and several authors have experimentally shown the possibility of this occurrence. Sticher (*Centralblatt f. Gynäkologie*, March 2, 1901) added to the water pure cultures of the bacillus prodigiosus, a germ not occurring in the normal vaginal secretion, and was able to recover it after the bath from the vaginas of both primiparæ and multiparæ while Stroganoff (*Centralblatt f. Gynäkologie*, Feb. 9, 1901) obtained similar positive results by using a chemical reaction (starch and iodide of potassium). This observer advises the complete abolition of the tub and the substitution for it of some modification of the Russian bath whereby the patient, seated or standing, is washed from above downward under a running stream, and does not remain in contact with the polluted water, and emphasizes the fact that by this means infection of the nipples which have been shown to be frequent portals of entry for germs is avoided.

As practical proof that this is not merely a theoretical consideration this author gives the statistics of the Imperial Maternity Asylum of

St. Petersburg where during the eighteen months in which this form of ablution has supplanted the tub and after exclusion of all other factors that might influence the results a drop of 7.4 per cent. in puerperal disease was noted.

A NEW GASTRIC FERMENT.

OVER forty years ago Marcet suggested that the stomach might possibly in addition to its proteolytic ferments possess the faculty of splitting off fatty acids from neutral fats. He was led to this conclusion because he had observed that it was only when free fatty acid was present that the bile was able to exert its emulsifying power on neutral fats which otherwise could not be acted upon. Since the fats of the food are neutral the presence of some agent adapted to break them up had to be assumed, and, since the steatolytic function of the pancreatic juice was unknown to him, Marcet ascribed this power to the stomach and detailed experiments on dogs that seemed to support his view.

Since then a few investigators have published corroboratory observations, but, on the whole, the matter has received very little attention and some text-books, like those of Bernstein, Foster and Hermann, entirely ignore the question while others, like Hammarsten and Gamgee, dismiss it with a bare mention of the possibility.

In testing gastric absorption by means of egg and grape-sugar emulsions, F. Volhard found that his preparations were acted upon in a way to recall these almost forgotten observations and on further experimentation (*Zeitschr. f. klin. Med.*, Vol. 42, Nos. 5-6) he was able to demonstrate the occurrence of very extensive breaking up of emulsified egg and milk-fat in the stomach. If a mixture of gastric juice and yolk of egg is allowed to stand at body temperature for from ¾-1¼ hours, the emulsion will be destroyed and the free fat be found floating on top of a clear fluid, but this result will not be obtained if the juice be previously boiled so as to destroy its ferments. The presence of the fatty acids may be easily proven by the preparation of an ether extract, while if the emulsion be simply destroyed by the high acidity of a concentrated artificial gastric juice no such decomposition takes place. The objection that the reaction may be due to some enzyme contained in the egg itself is met by the fact that boiling the gastric juice ruins the experiment, but in working with human stomach contents there is always risk that the retching produced by the presence of the stomach-tube may cause the regurgitation of enough pancreatic juice to invalidate the results, therefore most of the author's work was done on the pure secretion obtained from dogs having a Pawlow fistula. By macerating portions of pigs' stomachs it was found possible to obtain active glycerin extracts of the ferment and the chief seat of its secretion like that of pepsin was determined to lie in the fundus. In all, emulsions of thirteen different fats were subjected to the action of the ferment with the result that from 7 to 56 per cent. of fatty acid was obtained. A further significant observation is the fact that the presence of pepsin and hydrochloric acid in marked amounts inhibits and finally destroys the activity of the steatolytic ferment.

There seems little room for doubt of the accuracy of these observations and the existence of this addition to the list of enzymes will probably have to be regarded as an established fact, but just of how great practical importance the discovery will prove to be is hard to predict. Non-emulsified fats and artificial emulsions apparently are but little affected by the ferment, but when we consider the rôle played by the two most important natural emulsions, milk and yolk of egg, especially in sick and infant feeding, it is not unlikely that considerable practical benefit may accrue from this addition to our knowledge. That increased acidity inhibits the activity of the ferment perhaps explains the well-known repugnance for fats exhibited by patients suffering from hyperacidity, while the reason for the older observation of Pawlow that milk checks the formation of pepsin and HCl is made clear, and it seems that the gastric juice so produced is poor in these constituents but not in other ferments.

WHY ARE CHRISTIAN SCIENTISTS BAD RISKS?

THE daily papers have been inquiring on their own acount concerning the attitude of insurance companies towards Christian Science that the MEDICAL NEWS outlined in its editorial columns last week. Business is business, seems to be the motto of the agents who are interested in getting their commission on new policies; and as far as the reporters have been able to find out in their interviews, the sentiment is that if a good healthy Christian Scientist presented himself for examination with the intention of taking out a fat policy, there would be no reason to turn him down, simply because he abhorred physicians.

The *Sun* states, however, on the authority of a general agent of one of the companies, that "if a company wants to reject Christian Scientists it will be unnecessary to make any changes in the laws or in the form of application. The company can instruct its examiners that it considers Christian Scientists poor risks. All the examiners will do then will be to ascertain if an applicant is a follower of that cult. All applicants are asked when they were last attended by physicians, when and what was their last serious illness and who is their regular physician. In answering these questions the Christian Scientist will be pretty certain to reveal himself, especially if the examiner is on the lookout for him. All that the examiner will have to do then is to hear a little heart murmur or something like that and the home office will reject the application though the applicant produce the affidavits of dozens of medical men that he is sound as a dollar."

Another of our dailies, on the other hand, while telling facetious stories *apropos* of Christian Science and insurance companies, presents statistics calculated to allay the irritation of the insured at the increased risk and the possibility of increased premiums in companies preferred by Christian Scientists by showing that out of the 200,000 believers, in the country, some 6,000 only are candidates for insurance, and advances the easy don't-bother-me argument that if a man is privileged to commit suicide when his policy is two or three years old, he is privileged to die of self-imposed neglect in illness if he desires it.

But anecdotes of inconsistencies and hard-headedness among believers who collect accident insurance after being incapacitated by the "idea" of a broken leg, only serve to turn the attention of the public from two vital facts, viz., Christian Scientists do insure their lives, and they do die earlier than if they were properly cared for. This is difficult to prove to the layman; because to him disease is something that he "gets" and "gets over."

In reality sickness is the giving out of some organ, or the loss of some function. Expert advice in the matter of repairs is as absolutely essential as it is in the case of an ocean steamer that never dares move out of dock without its chief engineer. Physicians are chiefly engaged in strengthening weak organs and regulating disordered functions: they seldom "cure"; it is left to the all-sufficient to assume that responsibility. But they do keep folks a-going; and the result is, that after fifty years of teaching the value of sanitation, disinfectants, quarantine, treatment and sanitariums to the community, the length of life of the average man is much greater than it was, under similar conditions, half a century ago.

The Christian Scientists are bound to be fairly well because they live in a clean land; but otherwise they are bound to die sooner than if they knew what diseases were lurking in them, and slowly developing. There are any number of slowly developing maladies that if not promptly checked will terminate in death in from four to six years; diseases of the kidneys, diseases of the heart, diseases of the liver, the various forms of tuberculosis, and cancer, all insidious in their beginnings, and all requiring the microscope, and expert chemical and physical tests to discover. Among men and women over forty years of age, there is hardly one but that needs watching lest an incipient trouble becomes fatal. But with constant care, they may, they do, live to a good old age. On the success of physicians in warding off fatalities, is based the "expectation of life," which controls insurance rates.

The Christian Scientist who takes out his policy does so with the tacit assumption that he is not going to have any engineer to keep his organs in order, that he is not going to have an early diagnosis or any diagnosis whatsoever of his diseases made. He is bound to accept the physician's word if he is thrown out as a poor risk; but if he is accepted at thirty or forty as a good risk, he makes no pledge of good faith to the company, that he will not let the inevitable diseases and weaknesses of middle life run an unimpeded course to a fatal end.

The whole tremendous growth of life insurance is a thing of some fifty years. It is synchronous with the tremendous advance in science and the great lengthening of lives that would otherwise have succumbed to disease. The growth of Christian Science is a thing of a decade. The insured believers have not yet had time to see what effect a quarter of a century of neglect will have upon themselves and their families, nor have the insurance companies had a chance to prove how rapidly a "good risk" may degenerate into premature decay if he is not honest and sane in the preservation of his health.

Ten years, twenty years, thirty years, if the delusion does not die out as the kindred delusions of the century have done, will however show among Christian Scientists statistics of unchecked diseases with fatal endings that will startle the life insurance companies. Long before that time however they will have put the Christian Scientists into the class with the professional

bridge-jumpers and lion-tamers and all well-meaning fools that deliberately take their lives in their own hands; and charge them a premium in proportion to their belief.

ECHOES AND NEWS.

NEW YORK.

The Hokey-Pokey Man in New York.—In view of the fact that last week 4,000 hokey-pokey men were turned loose in New York City a recent ordinance passed at Brighton, England, is worthy of attention. The Bill provides, among other things, the infliction of a penalty of 40 shillings "on any manufacturer or dealer in ice cream, hokey-pokey or other similar commodity, who stores such articles in any room or cellar in which there is an opening to a drain, or who, in the manufacture, sale or storage of ice cream, does anything likely to expose them to infection or contamination." It would make an excellent subject for investigation by our vigilant Board of Health to determine just where and under what conditions our itinerant ice-cream vendors manufacture their cheap wares.

The New York Academy of Medicine.—A stated meeting will be held on Thursday, June 6th, at 8:15 P. M. The following program is announced: Presentation of the portrait of William H. Thomson, M.D., formerly President of the New York Academy of Medicine, by W. M. Polk, M.D.; "The Freezing-Point of Urine; Its Determination and the Inferences Which May Be Drawn From It," by J. H. Huddleston, M.D.; "The Early Recognition and Management of Arterial Degeneration," by Louis Faugères Bishop, M.D.

Medical Library of the Medical Society of the County of Kings.—This new library was thrown open on May 19, 1900, and now has over 30,000 volumes, 15,000 pamphlets and some 500 current medical periodicals. Its reading-rooms are open from 10 A. M. to 10 P. M., Sundays and holidays excepted, and its books are loaned to members of the County Society and other affiliated societies of Long Island.

Craig Colony Managers.—Dr. Pearce Bailey has been appointed a member of the Board of Managers of Craig Colony for Epileptics.

A Public Appeal for the West Side Tenement Children.—Those in charge of the Wilkes Dispensary connected with St. Mary's Free Hospital for Children, Ninth Avenue and Thirty-fourth Street, desire to enable the poor of the West Side to obtain sterilized milk for their babies. The Good Samaritan Dispensary has been enabled to do this for the poor of the East Side during the last few years, and has accomplished a great amount of good in the way of saving life and suffering. At St. Mary's there are rooms adapted for the work, doctors and nurses anxious to aid, and a large tenement-house acquaintance in the habit of visiting the dispensary. It is estimated that to put in a sterilizing plant, steam-pipes and water-pipes, sinks for washing bottles, and to supply bottles and milk and the extra help needed, will cost the first year about five thousand dollars. Those interested may call at the hospital, or communicate with Sister Catharine, No. 407 West Thirty-fourth Street.

Dedication of New Consumptive Sanatorium.—The County Sanatorium of the Montefiore Home already described in the Medical News was dedicated May 30th. It is at Bedford Station, Westchester County, about forty miles from this city, and now has a capacity of thirty patients. Since its first opening three years ago, through the generous gifts from the patrons and friends of the Montefiore Home, enough money has been raised to go ahead with the construction of new buildings, which consist of a central administration hall and two pavilions on each side, the group presenting a front elevation of about 419 feet, and having accommodation for 150 consumptive patients, men and women, especially poor people, without regard to race or creed, who have no other place to go. The buildings are of frame, two stories in height, and Colonial in exterior design. The full cost of the land and grounds will foot up about $250,000. The Sanatorium fund was originally started by two $25,000 gifts by Lyman G. Bloomingdale and Jacob Schiff, the latest large contribution being $40,000 from Leonard Lewisohn.

Loomis Sanatorium Buildings.—The chapel, new administration building and charitable annex were opened Monday last. Drs. William M. Polk, Henry P. Loomis and others were among the speakers.

Mt. Sinai Corner-Stone Laid.—The laying of the corner-stone of this hospital which is to be one of the most palatial in this city of beautiful hospitals took place last week with appropriate ceremonies. Among the speakers were Hon. Benjamin B. Odell, Randolph Guggenheimer, Seth Low, Edward Lauterbach and Dr. Abraham Jacobi. President Low of Columbia spoke of the foundation of Columbia College and its early association with hospital work in that the dean of the medical faculty of Columbia in 1769, Dr. Samuel Bard, called attention to the need of a public hospital in that city. Dr. Low said that he was glad to represent the same idea in the consummation of this magnificent design for the establishment of the new Mt. Sinai Hospital. Dr. Jacobi said in part:

"For most of you the definition of a modern hospital is a place to which poor sick people, men, women, and children, are carried with their pains and ills and aches and dangers to have them soothed, relieved, or removed. That is correct. But a modern hospital is no longer

the table under which 'the dogs eat of the children's crumbs.' That is what it was when incipient civilization, represented either by religious orders or by the buddings of a dawning sense of humanitarian responsibility, found it necessary to offer some aid to indigent and helpless sick fellow-creatures. A modern hospital, however, is no longer a dispenser of 'crumbs.' In it the inmates, rich or poor, enjoy the superior advantages of wealth, ingenuity, learning, and unceasing watchfulness.

"And now I will tell you in a few words of some of the points of view from which we doctors look upon a hospital. Ours is the vocation to relieve pain, remove or shorten disease, preserve limbs, save lives; or, if all that cannot be done, to soothe suffering, or render inevitable death more placid or endurable. Moreover, have your political economists ever calculated what the successful efforts of a hospital doctor or a doctor in general are worth financially to the individual and to the community? A child, an adolescent or adult dead is so much loss of capital spent on raising them; every day or week of illness that is lost to remunerative labor is so much capital squandered, and a detriment to the national wealth. Whoever dies before the physical necessity of advancing age sets a natural end to his existence is a loss to humanity.

"At the same time, a hospital is a school for doctors who learn and profit in the interest of mankind from collected and collective experience. It is a school for nurses whose very existence was not dreamed of twenty-seven years ago, before the first training school was founded in connection with Bellevue Hospital; a school for the patients and their families, by what they are taught, during their own sufferings and recovery, of cleanliness, of resources, and of preventive or curative measures: a school for the medical world abroad by the scientific contributions emanating from the institution, either individually or collectively, in the shape of reports."

Provisional Program of Clinical Days at the Albany Hospital, July and August, 1901.—Tuesday, July 2d, Introductory address by Albert Vander Veer, M.D., senior surgeon to the hospital, followed by Demonstration clinic in surgery, diagnosis and operations, by Albert Vander Veer, M.D., and Willis G. Macdonald, M.D. In the afternoon, Bender Laboratory. General remarks on the use of the microscope. Method of examination for the tubercle bacillus, by George Blumer, M.D.; Clinical lecture on chronic nephritis, by Samuel B. Ward, M.D.

Tuesday, July 9th: Address in clinical gynecology, by James P. Boyd, M.D., Demonstration of cases in the surgical wards, by W. G. Macdonald, M.D., Practical demonstration of methods for sterilization of dressings, instruments and water adapted to private practice, by C. H. Richardson, M.D. Afternoon, Bender Laboratory. The microscopic examination of urine: The significance of blood, pus and crystals, by A. W. Elting, M.D., Clinical lecture on locomotor ataxia, by Henry Hun, M.D.

Tuesday, July 16th, Demonstration of the use of the Roentgen ray in the treatment of fractures and dislocations, by William Hailes, Jr., M.D., Clinical demonstration in abdominal surgery, by W. G. Macdonald, M.D., Improved methods in the application of plaster-of-Paris dressings for the treatment of deformities, by A. W. Elting, M.D. Afternoon, Bender Laboratory. The microscopic examination of urine; the origin and significance of casts, by A. W. Elting, M.D., Application of the modern instruments of precision for diagnoses, by H. Van Rensselaer, M.D.

Tuesday, July 23d, The Roentgen ray in the diagnosis of foreign bodies (lodged), of biliary and renal calculi, of tumors, of diseases of the osseous system, by William Hailes, Jr., M.D., Demonstration and diagnosis clinic in surgery, with operations, by Albert Vander Veer, M.D., and W. G. Macdonald, M.D. Afternoon, Bender Laboratory. The methods of blood examination; red blood-corpuscles, leucocytes, hemoglobin, by A. W. Elting, M.D., Modern methods of quarantine and disinfection, by Joseph D. Craig, M.D., health officer of the city of Albany.

Tuesday, July 30th, Clinical demonstrations in dermatology, by Arthur Sautter, M.D., Catheters: their care and preservation, catheterization in stricture and enlarged prostate, by W. G. Macdonald, M.D., Demonstration of methods in infant feeding: the care of infants, at St. Margaret's Home, by H. L. K. Shaw, M.D. Afternoon, Bender Laboratory. The diagnostic value of blood examinations: anemias, leucemias, infectious processes, etc., by A. W. Elting, M.D., Modern methods in the diagnosis of cancer of the stomach, by A. MacFarlane, M.D.

Tuesday, August 6th, Demonstration of the obstetrical methods employed in the Albany Hospital, by William H. Happel, M.D., Diagnosis clinic in pelvic and abdominal diseases, examinations under anesthesia, by W. G. Macdonald, M.D., The treatment of deformities of the feet; tendon transplantation, by Arthur W. Elting, M.D. Afternoon, Bender Laboratory. The value of uterine scrapings in diagnosis, by George Blumer, M.D., Clinical demonstration in gastro-enteric diseases, by Leo H. Neuman, M.D.

Tuesday, August 13th, Methods of sterilization with particular reference to their adaptability to the wants of the general practitioner, by C. H. Richardson, M.D., Clinic in gynecology and abdominal surgery, by W. G. Macdonald, M.D., C. H. Richardson, M.D., and A. W. Elting, M.D. Afternoon, Bender Laboratory. The significance of the Widal reaction; the methods and significance of examinations for the gonococcus, by George Blumer, M.D.,

Clinical lecture on chorea and choreiform affections, by J. M. Mosher, M.D.

Tuesday, August 20th, Demonstration clinic in diseases of the nose and throat, by Arthur G. Root, M.D., Demonstration of cases in the surgical wards of the hospital, Demonstration of the use of the endoscope and cystoscope in diseases of the genito-urinary tract. Afternoon, Bender Laboratory. The value of bacteriologic examinations in cases of suspected diphtheria, with remarks on antitoxin, by A. W. Elting, M.D., Rheumatism and rheumatoid affections, by A. MacFarlane, M.D.

Tuesday, August 27th, Demonstration clinic in diseases of the nose and throat, by Arthur G. Root, M.D., Clinic in surgery, by W. G. Macdonald, M.D., A. W. Elting, M.D., and C. H. Richardson, M.D., Demonstration of clinical methods in diseases of the eye and ear, by C. S. Merrill, M.D. Afternoon, Filtration Plant. Bacteriological examination of drinking water; its value and demonstration of methods employed at the Albany filtration plant, Demonstration of the methods for collection, transportation and the physical and chemical examination of potable water, by Willis G. Tucker, M.D.

Physicians who desire further information in reference to the above program can obtain full details by addressing Dr. Edgar A. Vander Veer, 28 Eagle Street, Albany, N. Y.

State Civil Service Examinations.—The following position is open for competitive examination, June 15, 1901. Competitors must be at least twenty-one years of age and citizens of New York State, except as otherwise indicated: Assistant Superintendent State Hospital for Crippled and Deformed Children, Tarrytown, N. Y. Salary about $1,200 per year and maintenance. This officer is to be the business manager and steward of the institution. No medical knowledge is required. Experience in care of buildings and grounds and management of institutions and some knowledge of accounts desired. Subjects of examination and relative weights: questions on the duties of the position, including care and management of institution, purchase of supplies, accounts, etc., 6; experience and education, 4.

PHILADELPHIA.

Reception to Dr. Wyman.—Dr. Walter Wyman, Surgeon-General of the United States Marine-Hospital Service, was given a reception by the Medical Club of Philadelphia May 23d, about 150 physicians being present.

Medico-Chirurgical Commencement.—The annual commencement of the Medico-Chirurgical College was held May 25th. The graduates numbered 115—69 in medicine, 25 in dentistry, and 21 in pharmacy.

Pennsylvania State Medical Society.—The date of the annual meeting to be held in Philadelphia this fall has been changed from September 17-19 to September 24-26.

First Woman Physician in Philadelphia.—Dr. Hannah W. Longshore, the first woman to practise medicine in Philadelphia, celebrated her eighty-second birthday, May 23d. She is a graduate of the Women's Medical College of this city.

Protest against Hospital.—Prominent citizens of Narberth have protested against the locating of the pay hospital for contagious disease in that borough. No site in this city could be secured and 5½ acres have been purchased at the above location.

Typhoid Fever in West Philadelphia.—An epidemic of typhoid fever is present in West Philadelphia. Of the 142 cases reported last week more than one-third were from two wards in that section. Analyses of milk and water have been made, but the source of infection has not yet been discovered. An inspection of the sewers is contemplated.

Streptothrix Infections.—At the meeting of the County Medical Society May 22d Dr. J. H. Musser, the retiring President, delivered an address on the above subject. He spoke of infections of this class other than actinomycosis and madura foot. The lungs, brain and skin are the organs most frequently involved. From the clinical standpoint they present little that is new. Pulmonary involvement is often hidden under tuberculous symptoms. The findings of the streptothrix determines the diagnosis. Dr. Musser concludes that these infections are probably overlooked in many instances. Many of the so-called sterile abscesses may be streptothrix infections. Abscesses of the brain especially those without fever may also be due to the same cause.

CHICAGO.

Chicago Eye, Ear, Nose and Throat College.—Dr. Joseph C. Beck has recently been elected to the faculty of this institution as Pathologist and Professor of Otology.

Dr. Senn's Race against the Sun.—Dr. Nicholas Senn will devote his summer vacation to a ninety days' trip around the world. He will travel in an easterly direction, and the journey has been christened by him as "a race against the sun." The same phrase will form the title of a book, in which form letters to the *Chicago Tribune* will appear later. He will be accompanied by Dr. Daniel R. Brower, his colleague at Rush Medical College, and two other professional acquaintances.

Illinois Charitable Eye and Ear Infirmary.—Dr. Charles L. Enslee, for nine years otologist at the institution, has been asked to resign, and Dr. Norval H. Pierce has been named as his successor. The resignation of Dr. Wm. L. Noble, Surgeon-in-Chief of the eye department of the hospital, also has been requested. In connection with the removal of the two phy-

sicians, it is announced by the new Board of Trustees that the old Board of Medical Control, which was discarded as obsolete for four years, again is to be put in charge of the hospital. This institution was founded by Dr. Edward L. Holmes in 1858, and more than 250,000 poor persons have been treated in the hospital during its forty years of existence.

Appointment of Dr. Campbell.—Dr. O. Beverly Campbell, of St. Joseph, Mo., has been appointed on the gynecological staff of the Post-Graduate Medical School.

Five-Year Medical Course.—The Northwestern University Medical School, of this city, has added one year to its course for the benefit of fourth-year students and practitioners. This course will be inaugurated in October, 1901. Thirty-three per cent. of the students graduated from regular four-year courses have secured at the time of graduation appointment as internes in the various hospitals. The object of this additional year is to furnish to those students who have not been successful in obtaining interneships a more practical course than is compatible with the diverse routine work of the third and fourth years.

Illinois State Medical Society.—The fifty-first annual meeting was held at Peoria, May 21, 22, and 23, 1901, under the presidency of Dr. George N. Kreider, of Springfield. The Committee on Medical Legislation was empowered to draft a bill providing for a board of medical examiners in Illinois, the Committee to consult such laws as are operating best in other States. A resolution was offered and adopted that a bill be introduced at the next meeting of the Legislature requiring that the true names and quantities of the ingredients be plainly printed on each package of patent medicines and nostrums offered for sale. The Legislative Committee was requested to attempt to pass a bill forbidding in anywise exhibitions of hypnotism for the purpose of obtaining money.

Epileptic Colony.—The Legislative Committee was instructed to use all its power to secure the location of an epileptic colony in Illinois which was provided for by a bill passed by the Legislature two years ago.

Sanatorium for the Tuberculous.—The matter of securing legislation for the establishment of a sanatorium for the tuberculous was referred to a special committee which will report next year.

School of Graduation No Bar to Membership in State Society.—After considerable discussion, a resolution was adopted, that school of graduation shall be no bar to membership in the Illinois State Medical Society, providing such physician is recognized by the local society as qualified and not claiming to practise any exclusive system of medicine.

Officers of the State Society.—The following officers were elected for the ensuing year: President, Dr. T. J. McAnaly, Carbondale; First Vice-President, Dr. M. L. Harris, Chicago; Second Vice-President, Dr. J. W. Hensley, Peoria; Treasurer, Dr. Everett J. Brown, Decatur; Permanent Secretary, Dr. E. W. Weis, Ottawa; Assistant Secretary, Dr. Charles Dewey Center, Quincy. Quincy was selected as the place for holding the next annual meeting.

GENERAL.

Christian Scientists' Mecca and Medina.—It seems that the Massachusetts House does not desire to exclude Christian Scientists, or any of the so-called irregular practitioners, from the healing field, and has amended the Senate Medical Practice Bill accordingly.

Rhode Island Medical Society.—The ninetieth annual meeting of this Society will take place Thursday, June 6, 1901, in the Masonic Building, Providence. The annual address will be delivered by Dr. G. Alder Blumer, the title being "The Yesterday and To-day of Mental Medicine." Among the papers to be read are: "Etiology of Acute Pancreatitis in Children," by Dr. E. D. Cheseboro; "Simple or Transient Glycosuria," by Dr. S. A. Welch.

American Laryngological Association.—The twenty-third annual meeting of this Association was held in New Haven Tuesday, Wednesday and Thursday of this week. Dr. Henry L. Swain, of New Haven, was in the chair. President Arthur T. Hadley, of Yale, delivered the address of welcome and Dr. Swain read the president's address. Papers were read by Dr. Jonathan Dwight, of Brooklyn; Dr. A. Coolridge, Jr., of Boston; Dr. John O. Roe, of Rochester; Dr. Arthur Ames Bliss, of Philadelphia; Dr. S. Solis Cohen, of Philadelphia; Dr. Henry L. Wagner, of San Francisco; Dr. J. Edwin Rogers, of Chicago; Mayo Collier and W. F. Chappell, of New York; W. E. Cassellsbury, of Chicago; Emil Mayer, of New York, and J. H. Bryan, of Washington. The members visited the Yale psychological laboratory at the close of the day's session. The annual reception was tendered by President Hadley Tuesday evening.

New Vienna Hospital.—The comprehensive plans for the reconstruction of the Vienna General Hospital are reported to be in active stages of consummation. It is proposed to spend no less than $10,000,000 upon the improvement of hospital accommodations in Vienna, and the requisite permission has been secured from the Town Council. The Wiener Allgemeines Krankenhaus, in the Alserstrasse, which, with its many clinical institutes, and its concentration of material for clinical observation and research, is one of the leading public hospitals in Europe. Of late the growing demand for space, and the disturbances due to street traffic, have caused many complaints.

The late Professors Billroth and Albert, among others, protested vigorously, but all they could achieve was the erection of one or two temporary clinical institutes within the old hospital, as the enormous cost of a radical reform seemed prohibitive. Now it has been decided to remove two asylums, which are within a reasonable distance of the hospital, and appropriate their sites for new medical buildings. There is room for forty pavilions, with accommodation for two thousand patients, and a number of clinical institutes. The Medical School will then be one of the largest in the world, but it will be a long time, perhaps ten years, before the whole system is in working operation.

Leper Hospital Burned.—The Plantation House on the Elkhorn Plantation, Jefferson Parish, Louisiana, just purchased by the Board of Control of the Leper Home, and to which it was proposed to move the lepers now confined at Indian Camp, was burned by incendiaries at an early hour May 23d. It is recognized generally that the building was burned by persons in the neighborhood to prevent removal of the lepers there. Bitter opposition has existed to the establishment of a leper house in a thickly populated neighborhood.

Physicians Strike.—Another strike of physicians is reported in German newspapers. It appears that there exists at Bamberg, Bavaria, as in many other cities, a Krankenkasse, or mutual insurance association against illness. It has 800 members, who are entitled to twenty weeks of medical treatment a year, and the association has prospered so well that it has over $32,000 in its treasury. In 1893 an arrangement was made with local physicians, who agreed to take care of the members at a cost not to exceed twelve cents a visit, the average charge being seven cents. Evidently the physicians did not have the best of this arrangement, yet there was no protest on their part until the association began to add insult to injury. A mountebank and hypnotist delivered a lecture in which he assailed the medical profession in the most abusive language, and extolled his own method of assisting nature in curing disease. Some of the members of the association thereupon wished to accept this fellow as one of their doctors. The physicians promptly refused to acknowledge him as a colleague, both on legal and on professional grounds. When, nevertheless, in spite of protest, a majority of the members voted to accept this healer (who objected to the use of any medicine), the physicians promptly threw up their contract, agreeing, however, to continue treatment of such patients as they had charge of at the time.

Dr. Ohlmacher and the Ohio Hospital for Epileptics.—On May 1st Dr. A. P. Ohlmacher, Director of the Pathological Laboratory at the Ohio Hospital for Epileptics at Gallipolis was summarily discharged by Dr. H. C. Rutter, Manager of the Hospital. It now develops that immediately on learning of this action Governor Nash requested Dr. Rutter's resignation, a step he had long contemplated on account of the personal and political indiscretion of the Manager, but from which he was deterred by his respect for the opinions of the medical profession. Dr. Ohlmacher's discharge seems to have been the signal for final and speedy action on the Governor's part.

At a meeting of the Board of Trustees of the Ohio Hospital for Epileptics, May 17th, Dr. H. C. Rutter, Manager, formally tendered his resignation which had been requested by Governor Nash. At this time an effort was made by Dr. Rutter to obtain the support of the Trustees in his discharge of the Director of the Pathological Laboratory, Dr. A. P. Ohlmacher, but a letter from the Governor to the Board of Trustees was read expressly forbidding this action.

Obituary.—Dr. Theodore F. Rumbold, known in America and Europe for his contributions to medical literature and researches in nasal surgery, died in St. Louis last week, at the age of seventy-one. He was a native of Aberdeen, Scotland. He came to America in 1834.

Dr. Conrad Wienges, a Jersey City physician, died at his home, 473 Jersey Avenue, early yesterday morning. He was born in Charleston, S. C., in 1848.

Dr. Marie J. Mergler recently died in Los Angeles, California, of pernicious anemia. She was one of the leading woman physicians of Chicago and was Dean of the Woman's Medical College. Dr. Mergler was born in Bavaria. In 1876 she matriculated at the Woman's Medical College of Chicago, graduating in 1879. Soon afterward she was elected lecturer on Materia Medica at her Alma Mater, and later went to Zurich to study for a year. In 1881 she returned to Chicago, and began to establish a general practice. Upon the death of Dr. William H. Byford, Dr. Mergler was appointed his successor as Professor of Gynecology of the Woman's Medical College. Dr. Mergler was one of the attending surgeons at the Woman's Hospital of Chicago, and gynecologist to the Wesley Hospital. She served as Professor of Gynecology at the Post-Graduate Medical School, and when appointed on the attending staff of the Cook County Hospital was the second woman to hold such a position. Dr. Mergler was elected head physician of the Hospital for Women and Children soon after the death of Dr. Mary Thompson, its founder.

Dr. Jane Kendrick Culver, one of the most successful of the women physicians of Boston, died Monday at her home. She was born near Enfield, Mass., and was graduated at the Boston Homeopathic College in 1878.

CORRESPONDENCE.

OHIO STATE EPILEPTIC HOSPITAL CONTROVERSY.

To the Editor of the Medical News:

Dear Sir: Your cordial response to my circular letter of May 4th was most gratifying and on behalf of those, like myself, who are engaged in State laboratory work and who are hampered by institutional or political restrictions I beg to thank you.[1] Since issuing that circular the events in our unfortunate local affair have followed rapidly. It is now certain that within twenty-four to thirty-six hours after he discharged me Dr. Rutter's resignation was asked for by Governor Nash. It develops that the Governor had only paused in this contemplated step fearing that Dr. Rutter's removal would embarrass the medical-scientific work of the Laboratory and thus offend the medical profession. On the 17th inst. our Board of Trustees met and here Dr. Rutter endeavored to obtain support for his action against me, but was met by a letter from the Governor expressly forbidding my disturbance.

Dr. Rutter was appointed here by the then Governor of Ohio, now President William McKinley, and Dr. Rutter's acts of offensive political partizanship have attracted attention in political circles from those in Gallia County to the President himself, thus giving the affairs of this institution an unusual prominence. It must, therefore, be evident that Governor Nash's respect for our profession and his sympathy with the scientific spirit for which the Laboratory stands make a profound impression politically; and that individual action, medical society action (like that of the Ohio State Medical Society, May 9th, commending Governor Nash for his "broad-minded statesmanship") or the voice of the medical press are very timely and will be the means of advancing the movement for State scientific medical research in political estimation.

I am glad that personalities may now be laid aside and that we may all now look to the results of our trouble here broadly and as offering an exceptional opportunity of advancing the interests of scientific medical progress.

A. P. Ohlmacher.

Gallipolis, Ohio, May 18, 1901.

To the Editor of the Medical News:

Dear Sir:—My attention has just been called to a circular letter written by Dr. A. P. Ohlmacher and bearing date, May 4th. The letter is so full of misstatements and direct falsehoods that I cannot in justice to myself and the profession permit it to remain unanswered. In the first place Dr. Ohlmacher states, "I received a letter from Dr. H. C. Rutter, Manager, etc., discharging me from my position of Director of the Pathological Laboratory in this Institution. This is untrue as the letter spoken of will show. It was as follows:

Ohio Hospital for Epileptics, May 1, 1901.

Dr. A. P. Ohlmacher, Gallipolis, Ohio:

Dear Doctor—Reckoning your agreement with the Hospital for services, to be on a yearly basis, the present term will expire the middle of the current month. I consider it my duty to inform you that the management has decided to make other arrangements for the ensuing year, and therefore its business relations with you will terminate at that time.

Wishing you all the success your genius merits, I am, Yours respectfully,

H. C. Rutter.

It will be seen that he was not discharged but notified politely that he would not be re-appointed for another year. In the next place, with a characteristic lack of modesty, he denounces his failure to be reappointed as an assault by Dr. Rutter on the Laboratory and takes advantage of a political warfare that has been waged against Dr. Rutter for years to make insinuating remarks to his discredit. He fails to state that the Laboratory is a result of Dr. Rutter's continuous labor for eight years. That it had been in successful operation for more than three years before Dr. Ohlmacher's connection with it, and that he owed his employment and continuous service entirely to the efforts of Dr. Rutter against the unceasing assaults of the political tricksters with whom Dr. Ohlmacher joined his fortunes as soon as he felt that they had a chance of success. In the next place he insults the profession by insinuating that he is the only available man capable of doing the work required in the position, and that a change implies disorganization and ruin. The absurdity of his position will be readily appreciated when it is known that Dr. Ohlmacher has had absolutely nothing to do with the establishment or maintenance of the Laboratory. He was an employé simply and purely, received an ample salary, was supplied with the best equipment obtainable, and got all the credit in the Medical world his work entitled him to. The labor of sustaining the Laboratory, securing appropriations for its maintenance, and his salary, and receiving all the criticisms of the politicians, and many state officials was my part of the work. This division of labor and rewards should be some indication of my unselfish interest in the success of the Laboratory.

Now as to the reasons for Dr. Ohlmacher's failure of re-appointment. Broadly stated his services were unsatisfactory for the reason that he constantly neglected his work, and in the opinion of his employers did not earn the salary paid him. This matter has been a subject of discussion in the Board of Trustees for more than one year and hence it cannot be said that a conclusion was hastily reached. In addition to his neglect of work his disposition has been so intensely disagreeable that he has been a focus of continual discord and inharmony. He states in his letter that seven contributions have been made from the Laboratory in the year past. This is absolutely untrue, and should not be received without at

[1] Introductory phrase a gratuitous one—no response having been sent.

least mention of the contributions and where they appeared. It is true that he spent several months compiling sections for a Text Book on Pathology and while so doing absolutely neglected the research work he was employed to perform.

In his circular letter he appeals for assistance in overturning the acts of his employer for four years and coercing by the authority of the Governor the men who have built the Laboratory, successfully started it, and secured all of the aid to maintain it. In effect he seeks to ally the Medical Profession with a band of unscrupulous politicians who are at present using him to help disorganize the present management and who will fling him aside as soon as their purposes are accomplished.

The only question involved in this matter is whether or not an employer who is charged with the responsibility of men may have the right to change an employé without having his motives criticized upon the unsupported statement of the individual dislodged. The Laboratory has not been threatened by any body except Dr. Ohlmacher's new found political manipulators who will probably succeed in overthrowing its founders and supporters, and it is in aid of this gang that he invokes the assistance of the medical societies and periodicals.

H. C. Rutter.

Gallipolis, Ohio, May 20, 1901.

SOCIETY PROCEEDINGS.

AMERICAN PEDIATRIC SOCIETY

Thirteenth Annual Meeting, Held at Niagara Falls, May 27, 28 and 29, 1901.

First Day—May 27th.

President's Address.—The President, Dr. Wm. D. Booker, of Baltimore, spoke of the loss sustained by the Society since its last meeting in the death of Dr. J. H. Fruitnight, one of the most useful and highly esteemed members of the profession. The President's formal talk was devoted to a review of the early literature of cholera infantum.

History of Cholera Infantum.—The disease was first noticed as an entity by American observers. In Colonial days it was a common affection of children living along the Atlantic Coast and was at one time believed to be peculiar to that locality. Rush described it in 1777, and it went by various names during the succeeding half century, during which time it was practically unappreciated in Europe. Even today there remains in some degree a semi-traditional neglect of digestive disorders by medical men; the old tendency survives of relegating these troubles to mothers and nurses; pathologists have scarcely given proper attention to the subject. What we know of the disease we owe chiefly to the clinician. Among European countries Germany was first to give attention to cholera infantum. France follows, but French writers of the early part of this century say the disease is practically unknown in their country, and they quote American authors on the subject. English clinicians remained indifferent to cholera infantum until the middle of the nineteenth century.

Etiology and Treatment.—These were first considered in the treatise by Rush, who also gave an accurate clinical history of the disease. In 1812 James Jackson gave a beautiful description of the wasting form of summer diarrhea in infants; his autopsies, in which he was assisted by J. C. Warren, were the first made in this connection, and served to establish the inflammatory condition of the alimentary mucous membrane. Howell in 1823 refers to atmospheric heat as a causative factor; the same subject is treated a little later by Cooke. Horner's description of ulcerated intestinal follicles, published in 1828, was of the greatest value. In historical order, the etiological factors considered were heat, dentition, worms, vitiated atmosphere, marsh miasm, the last named being referred to at a time when cholera infantum was classed with remittent fevers. In regard to treatment, calomel was a favorite drug among early writers, and stomach washing and intestinal irrigation were afterward introduced. To-day hygiene and careful dieting are the key-notes in prophylaxis and treatment.

Arteriosclerosis in a Boy.—This case was presented by Dr. Allen Baines of Toronto, who referred to the rarity of the condition. Holt refers to but seven cases. The present case is notable for the existence of "pipe-stem" arteries throughout the body. No history of syphilis could be obtained; the boy had had measles, but no other acute disease. He was a particularly healthy child. On December 8th he had three convulsions, vomited, and swollen cervical glands were noticed. Two days later he came to the hospital, and the large unhealthy ulcers in his mouth suggested cancrum oris. Antiseptics and styptics were used locally, chlorate of potash internally. On December 14th urinalysis showed 8 per cent. albumin; microscopical examination negative. Gums would bleed on slightest pressure. Repeated attacks of epistaxis occurred, which were controlled by suprarenal extract. Rigid arteries could be felt everywhere; the heart was enlarged, reaching left nipple line, and these conditions explained the frequent and almost uncontrollable hemorrhages. A vessel could be seen plainly spurting from the right side of the septum when epistaxis occurred. On January 7th, dyspnea and precordial distress; pulse 130; liver 3 inches below costal margin; heart impulse diffuse, apex located displaced downward and outward. January 8th abdomen tympanitic. January 10th, respirations becoming slower and slower, heart feeble. Death occurred at 10 a.m.

General Fibrosis Present.—Gross and minute examination after death showed general fibrosis. Margins of mitral cusps were slightly thickened; atheroma of aorta was marked; the

coronaries were hardened, and fibrosis had impaired the myocardium. In the kidneys the vascular changes were well marked, and the organs were shrunken, cortex narrow, surface lobulated. In the brain above were vessels found which were perfectly normal.

Pernicious Anemia in Infancy.—Dr. T. M. Rotch of Boston said that while clinical examinations of the blood had done much to differentiate diseases of the blood, the subject had not been exhausted. The instability of the blood-making organs in infants enhances the difficulty encountered in the diagnosis of cases during this period of life. Cabot's findings properly sum up the knowledge of the present day. It is argued that all anemias are secondary or symptomatic, but a class of cases can be separated which end fatally and for which no cause can be found. Pernicious anemia is rarer in infancy than in childhood. Up to 1897 only 25 cases were recorded occurring in patients under fifteen years; all were fatal. In 2,068 cases admitted to the children's wards of a Boston hospital no single case of idiopathic pernicious anemia is recorded. All recorded cases have been fatal except one case observed by Dr. Rotch and Dr. Maynard Ladd, an account of which Dr. Rotch presented to the Society.

Etiology.—There is no known cause and no generally accepted theory. Fatty degeneration of the heart, and an atrophic condition of the glands of the digestive tract are probably secondary, not primary. Failure has followed the attempt to find a specific micro-organism. Cabot, with justice, declares that to say merely that pernicious anemia is a disease of the blood-making organs is to admit that we do not know its cause; we know very little about these organs themselves. Hunter's theory is that of auto-intoxication from the intestinal tract. The ptomains which he isolated from the urine are probably due to the digestive disturbances which exist in anemias. Cases of carbon-monoxide poisoning add weight to the intoxication theory. Of the pathology it need only be said that in infants the conditions correspond to those in adults.

The Blood Changes.—The most important clinical lesions are in the blood, which shows on examination feeble coagulation; no formation of rouleaux; reduction of specific gravity; diminution of bulk; a fall of red-blood-cells to 2,000,000 or even to 1,000,000; hemoglobin reduced to 30, 20, 10 per cent.; total leucocytes may be high, and the finding of some myelocytes is not uncommon; average diameter of red cells increased; megaloblasts especially characteristic among the nucleated red cells that are found; oval and pyriform red cells are regarded as characteristic.

A Case Which Apparently Recovered.—One patient, a baby, was under observation from birth, when it weighed 7½ pounds and was in all respects normal. After the second day was fed with breast milk. Digestion normal at three weeks after slight temporary evidence of intestinal indigestion. At four months the child began to lose weight; indigestion marked. Taken off breast and modified milk substituted, first with 3.50 per cent. fat, 6 per cent. sugar, 1 per cent. proteid; later these percentages were increased to 4, 7, 2 respectively. Child gained one pound in ten days. At five months a mild attack of measles; recovery. At six months weighed 16¼ pounds; healthy in general. Some slight indigestion at irregular intervals was controlled and corrected by changes in composition of milk as needed. At eight months, pallor noticed. Nine months, milk increased to, fats 4 per cent., sugars 7 per cent., proteid 2 per cent.; improved: digestion normal. Then insidiously symptoms of anemia developed, rise of temperature, coryza, fretfulness, pallor, malaise. On November 4th, the child being ten months old, pallor was marked, temperature 100° F. Systolic murmurs developed; the face and hands and feet became puffy. No subcutaneous hemorrhage; no enlargement of spleen or lymph-nodes. Urine contained slight trace of albumin, no blood or casts. Edema could not be accounted for by condition of kidneys. The blood examination on November 5th was that of a severe secondary or a primary pernicious anemia, red cells 1,732,000, hemoglobin 30 per cent., leucocytes 9,200. No source of anemia could be traced. Milk was obtained from another herd of cows, though the earlier source of supply had previously given satisfaction and there was no reason to suspect it; the change made no difference; the child continued steadily to fail.

Treatment.—Brandy, careful feeding, cereals and broths were tried, but abandoned. On November 21st inhalation of oxygen was tried, at ten-minute intervals day and night; temperature subsided, pulse improved, apathy diminished. Dr. A. Jacobi saw the child two days after this improvement began. He suggested Liq. potass. arsen. and Ferratin, the latter as a substitute for the iron previously given in another form. In a week the arsenic was dropped as physiological reaction occurred. It was tried again and a second time was dropped. In no recorded case has oxygen been used so freely as in this instance. The improvement which occurred is shown by the tables which follow, representing a summary of repeated blood examinations made by Dr. Ladd with the coöperation of Dr. Cabot:

	Red Cells.	Hemoglobin (Per cent.)	Leucocytes.
November 21st (oxygen begun)	1,088,000	20	18,800
December 5th	2,000,000 +	35	10,800
January 2nd	4,216,000	70	11,000
January 30th	4,884,000	75	11,800
March 12th (nucleated red cells have disappeared)	5,270,000	80	

While the improvement in this case began from the time oxygen was first administered

under Dr. Rotch's direction, the latter does not regard the case as one which presents conclusive evidence of the value of this treatment, as cases no doubt occur which improve in the absence of treatment. Further experience is needed as the basis for scientific conclusions.

Prognosis.—Dr. Cabot regards the case as one of progressive pernicious anemia, and we must not be surprised if it goes the way of such cases. Yet to-day the patient, at eighteen months of age, weighs 20 pounds, has normal blood, and, so far as present examination can show, is a perfectly healthy child. The pathognomonic signs of progressive pernicious anemia were all present in this case; but Dr. Rotch believes that these signs lose some of their significance in infants owing to the activity of the blood-making organs in infancy.

Heart Murmurs in Infants.—Dr. Wentworth of Boston, taking up the question of heart murmurs in anemia, said he had been looking for so-called functional murmurs in babies under three years, and believed that they are very rare. It would be interesting to know whether the murmur which developed in Dr. Rotch's case still persists.

Dr. Wm. P. Northrup of New York declared that at the New York Foundling Asylum heart murmurs are common among children and infants who have no organic lesion. Thousands of such cases occur under three years of age; in fact an overwhelming proportion of heart murmurs in infants occur in the absence of valvular disease.

Dr. J. Lovett Morse of Boston said that rules of blood diagnosis which apply in adults do not hold good in infants. While in Dr. Rotch's case the blood examinations give fairly characteristic pictures of a pernicious anemia, or what would be so regarded in an adult, identical conditions of blood are met with in cases where the etiological factors are definitely known. Hence he could not concur in the prognosis which Dr. Cabot had given.

Dr. C. W. Townsend of Boston did not feel that there would be any return of the anemia in Dr. Rotch's patient. Two cases of extreme anemia in infants were recently under his observation. The diet in these cases had been insufficient, and one case promptly succumbed before treatment was well under way. In the second case, which like the first had been previously fed on modified milk, pasteurized and peptonized, the child improved as soon as a stronger diet was substituted.

Unusual Causes of Transient Albuminuria.—Dr. Dorning cited a case in which palpation of the kidney caused not merely albuminuria, but the appearance of casts in urine examined two hours after the palpation. One hour before this procedure the urinalysis had yielded negative results. A systematic investigation of this subject would be interesting.

Dr. F. A. Packard has seen a case of movable kidney in which evening albuminuria is a regular occurrence; after rest in the recumbent posture the amount of albumin is decidedly diminished. The kidney in this case is retained by a pad, and practically one can tell whether or not the pad is worn and is in place by examining the patient's urine.

Dr. Henry Koplik said that all cases of transient albuminuria should be carefully watched. Even Heubner does not insist upon the purity of cases of so-called functional albuminuria; there is always a reservation to the effect that a mild grade of nephritis may be present, or to put the matter differently, the possibility of a development of nephritis should be kept in mind.

So-Called Cyclic Albuminuria.—Dr. Frank Spooner Churchill emphasized the importance of alterations in blood-vessel walls, as well as changes in the blood itself, in the production of cyclic albuminuria. A plausible theory ascribes the vascular changes to previous inflammation. The influence of posture, diet and weather changes has been pointed out by various writers on cyclic albuminuria. The absence of definite knowledge of structural conditions is due to the fact that the condition is never fatal. Where a loss of elasticity has occurred in the glomerular vessels, these vessels may be able to functionate while the person is resting and recumbent; but an increase of pressure is followed by albuminuria. Both local and general factors are involved. Osler believes that a large proportion of cases of cyclic albuminuria get well.

Tendency to Kidney Trouble Should Be Controlled.—Dr. Churchill asked whether cyclic albuminuria might not be regarded as a manifestation of hereditary tendency in the Weissmann sense. If so, this suggests the proper treatment of these cases; the "tendency" should be prevented from developing into an actual condition. Dr. Churchill made an exhaustive study of a case of so-called cyclic albuminuria in a girl eleven years old. Eighty examinations of urine made at various hours during the day, over a period of many weeks, showed the frequent presence of albumin during afternoon hours, and its absence, as a rule, in morning hours and its disappearance during the evening. The patient passed a fair amount of urine constantly and showed not the mildest symptoms of uremia at any time. Urea was passed in good quantity. Of interest were the family history, pointing to cardiovascular trouble, and the personal history, which revealed a previous attack of measles, tonsillitis, and what the family physician called "catarrhal enteritis." The latter was possibly an abortive typhoid, as expert bacteriological examination showed, in the words of the bacteriologist, "incomplete reaction to Widal." In this case, the treatment has been a low nitrogenous diet, plenty of water, 5 grains of urotropin t.i.d., massage, and

light gymnastics. Marked improvement in the character of the urine has occurred. The case could not have been diagnosed nor would necessary treatment have been instituted if frequent urinalyses, at various hours and under various conditions, had not been made.

Epidemic in Children; Questionable "Malaria."—Dr. Rowland G. Freeman reported an epidemic at the New York Foundling Asylum. The cases all developed in the early summer of 1899 in a group of children occupying a certain section of the Asylum, near which in the spring of that year excavations had been made; stagnant water was allowed to collect in these excavations early in June. It was difficult, Dr. Freeman said, to reconcile this theory of causation with the mosquito theory, as the epidemic occurred too soon after the collection of this water to have permitted the development of the plasmodium in the mosquito. Malaria was suggested as an explanation of the epidemic, because (1) there was no evidence of gastro-intestinal disorder; (2) treatment with castor oil and diet did not give relief; (3) after unsuccessful attempts to demonstrate the specific organism in the blood of six patients, in a seventh the attempt succeeded; (4) the administration of 2 grains of quinine every four hours resulted in a subsidence of the fever in all the cases. The difficulty in early diagnosis arose from the vague nature of the symptoms. Irregular fever existed in all the cases, with maximal temperatures of 100.5° to 105° F. In two cases chills were marked; two had chilly sensations; eight had headaches; in six vomiting occurred. Meanwhile 76 children, who had shared with those first mentioned the playroom near the stagnant pools, were all becoming ill. Instead of waiting for the development of definite symptoms in these 76 children, the house staff administered to each child a daily dose of 2 grains of quinine; as no benefit resulted the dose was raised to 6 grains; recovery followed in every case.

Susceptibility of Children to Malaria.—This is well known, Dr. Freeman said, in malarial districts. In such localities, as extensive investigations have shown, infection is most common in children under one year of age. As age advances, the percentage of individuals in whose blood malaria can be demonstrated progressively falls.

Strangulated Appendix in a Child of Three Months.—Aside from the occurrence of acute fatal appendicitis in an infant, this case, reported by Dr. J. P. Crozier Griffith, showed on autopsy evidences of an earlier appendicitis from which the child had recovered. Shortening of the mesentery prevented the movement of half of the appendix, while the distal end moved without impediment; thus there resulted a kinking of the appendix, strangulation and gangrene. That inflammation follows obstruction of the lumen of this viscus is well known. Two cases previously seen by Dr. Griffith occurred in children of four years; a third case was in a child of three. In 228 cases of appendicitis reported by Fitz, twenty-two were found to have taken place in patients from ten months to ten years of age. The disease, common during adolescence, is uncommon under five years and especially rare in infants.

Persistent Laryngeal Stenosis.—Dr. Griffith reported a case which he said was of uncertain nature. After a diagnosis of laryngeal diphtheria by the family physician, the case failed to show any exudate; cultures made on the seventh and ninth days were negative. The patient was discharged after twelve days, but returned with a similar attack seven days later. Intubation gave relief. The patient, a child of twenty months, then developed and in due time recovered from pneumonia, subsequent to which another attack of laryngeal stenosis occurred. Five members of the same family have such attacks, and in every case the stridor persists night and day.

Diagnosis from Laryngismus Stridulus, etc.—The attacks differ from laryngismus stridulus in their persistency. Similar attacks have been known as the result of pressure by a tuberculous gland; but here the insertion of a tube would not have given relief. Pressure on the pneumogastric would produce only unilateral signs. Papilloma of the larynx sufficient to produce such stenosis would surely have been revealed on examination. Cultures excluded diphtheria. Acute laryngitis with spasmodic symptoms does not, as a rule, cause stridulous respiration for more than a day or two. In this case there was present at the outset a congestion of the laryngeal mucous membrane; there was a neurotic family history, and while a pronounced rachitic head was the only evidence of rachitis present, the latter element would have to be considered.

Edema Below Glottis.—Dr. B. K. Rachford had seen several cases of persistent laryngeal obstruction due to chronic edema located below the glottis. Tubes had to be left in place for several weeks. In one case a period of relief from laryngeal symptoms coincided with marked diarrheal trouble, so severe as to cause a loss of four pounds in a week. Probably there was some relation between this severe diarrhea and the temporary subsidence of the edema below the glottis.

Antitoxin in Doubtful Cases.—Dr. T. M. Rotch remarked that even where cultures failed to show the Klebs-Loeffler bacillus, and where no clinical symptoms of diphtheria could be made out, it might be wise to administer antitoxin. It is a common occurrence to get relief by means of antitoxin in cases where a positive diagnosis of diphtheria by bacteriological means has failed.

The Place of Cereals in Infant Feeding.—Dr. Henry D. Chapin's exhaustive paper at-

tracted marked attention. Dr. Chapin said that the chemical analysis of milk is not the only scientific basis for the comparison of one milk with another. It is essential to study carefully the behavior of the milk in the digestive tract. Cow's milk and woman's milk were intended by Nature for different digestive systems, and mere percentage modification of one does not make it the equal of the other for digestive purposes. Inasmuch as cow's milk forms solid curds and woman's milk flocculent curds, the curds of cow's milk intended for infants should be broken up mechanically. Cereal gruels mechanically break up curds of cow's milk, and their use is entirely rational. It is often advisable to make the standard diluent a digested gruel, as this not only breaks up the curds, but it exposes a surface of milk proteids and furnishes a certain amount of nourishment that is at once available for carrying on the work of digestion, taking the place of a part of the soluble proteids. Also, it furnishes a satisfactory substitute for milk when the latter must be withheld for a few days. A great variety of food can be supplied to an infant by means of digested gruels. The expense is trifling, and the tendency is to get back to milk feedings as soon as possible, and not to keep on indefinitely with a diet of carbohydrates, as when most infant foods are used.

The Separation of the Whey Proteids.—Dr. Rotch, who has heretofore maintained that a finer coagulum is not obtained by the use of barley-water, said that he had modified his views; starch in proper percentage does give a finer coagulum, as recent experiments at the Massachusetts General Hospital showed. But it is not at all necessary to give starch for this purpose. A more efficient measure is not to give the whole proteid of milk, but to separate the whey albumins, and to increase their proportion in the modified milk administered. By this means we obtain a finer curd than results from the use of the whole proteid plus barley water.

Necessity for a Classification of Infants.—Dr. Koplik, from a clinical viewpoint, emphasized the need of separating healthy children from sick children in considering problems of feeding. Furthermore, infants, acutely ill, must be distinguished from those chronically ill. In healthy infants it is rarely necessary to do more than to give a modified cow's milk, corrected as to percentages. In acutely sick infants no milk is satisfactory; but if here dextrinized gruels be added, the infants increase in weight and diarrhea ceases. In the chronic cases there is a prolonged intestinal toxemia. No matter what modification of milk is used the intoxication proceeds. Keller has attempted to dextrinize milk without the addition of a cereal, but concludes that the latter ingredient is essential. The author does not advocate the use of dextrinized gruels in all cases, however. The individual intestine calls for consideration. Dr. Chapin's method of acting on milk has given excellent clinical results.

Dr. L. Emmett Holt called attention to the importance of radical changes of diet for the relief of intestinal symptoms in infants. Minor alterations in percentage he believes to be of slight relative importance. The ordinary practitioner's error is not a failure to change from one per cent. proteid to three-quarters per cent., or vice versa; it is a gross error, a failure to see things radically wrong. When a baby is persistently sick on starchy foods, take him off that diet altogether and he will do better.

Dr. Winters maintained that the relative proportions of fat and proteid were of far greater importance than the actual percentage of proteid used. A baby will get ill if given 3 per cent. fat: 1 per cent. proteid; the baby will recover when the proportions are altered to 3.50 : .50 or 4.00 : 1.00.

Dr. Saunders would not say that cereals were essential in dieting normal cases; experience, however, had convinced him that in the sick diet they were invaluable.

Amaurotic Family Idiocy.—Dr. A. C. Cotton found 36 recorded cases of amaurotic family idiocy. The name was suggested by Sachs. In its symptomatology the constant findings are to be differentiated from those which may or may not be present. The former include, in the early stages, idiocy, changes in macula lutea, paralysis; early death is common. Amaurosis is always present. In the absence of ocular symptoms a case could scarcely be diagnosed. The inconstant nervous symptoms embrace nystagmus, strabismus, spasticity, paralysis, tremors, exaggerated reflexes, hyperacusis, hyperesthesia. The etiology of the condition is still sub judice. No vascular or inflammatory changes have been found. Hirsch's theory of infection derived from mother's milk is somewhat favored by Jacobi, but in the two cases of Sachs the children were not breast fed.

Clinical History of a Case.—R. F., two years of age. Referred by physician as a case of rachitic malnutrition. Father's cousin's child died in convulsions at 20 months; was blind; never able to sit up. No consanguinity in parents; no specific history. Birth and gestation normal. At 6 mos. had bronchitis; no exanthem. First tooth at one year. Could stand with support at nine months; later muscular disability developed. Examination showed head measuring 19 inches; blank expression; pupils unequal; convergent strabismus; high arched palate; unable to hold head up; claw hands; spasticity in extremities; extremely sensitive to sight and touch; nystagmus. General convulsions occur, during which hands turn inward; each spasm lasts 15-60 seconds, followed by moaning. After 8 to 10 convulsions irritability disappears;

rest restores the convulsive tendency. The fundus showed normal disks, choroidal rings distinct and normal. The chief feature of the eye-ground was a brownish disk occupying region of macula, surrounded by a whitish zone, and densest at its center. The patient had difficulty in swallowing; this constantly increased, resulting in inanition and death.

The Little Finger of the Mongolian Imbecile and of Normal Children.—Dr. J. Park West of Bellaire, O., having had his attention called to the outward bowing of the little finger, said to be characteristic of the Mongolian imbecile, examined the little fingers of 605 children (296 males and 309 females), the ordinary children of an industrial community which included a mixture of nationalities. He found that 118 had straight little fingers, 179 fingers slightly curved, 199 distinct curvature, and 109 marked curve. The curve in the last group corresponds to what has been regarded as the peculiar possession of Mongolian imbeciles. In mental capacity the four groups of children are indistinguishable. On the other hand, Dr. West has seen 9 Mongolian imbeciles, and only one of these showed markedly curved little fingers; the fingers of the remaining 8 were exactly like those of the other three groups of normal children.

Maternal Impression.—A report by Dr. B. K. Rachford described a case in which stitch scars, resulting from an operation for appendicitis on a woman during the third month of her pregnancy, were reproduced in her child, being first noticed in the child when the latter was a year old. Dr. Rachford saw the child at birth and treated it during its first year for slight ailments. From the twelfth to the eighteenth month the marks increased in distinctness, and have since remained at a standstill. Dr. Rachford's belief is that the case is an authentic one, and that the marks may be the result of the tension on the stitches in the mother, who vomited violently for several days after her operation.

Pathological Anatomy of Cretinism.—A cretin aged six years, was treated by Dr. Frederick A. Packard and Dr. A. Hand, Jr., with thyroid extract, beginning with 2 gr. doses of the extract and gradually diminishing the dose to ¼ gr. During this time the patient lost in weight but gained height and improved mentally. While under treatment the patient developed high temperature, emaciation and anemia and died with signs of an acute illness. Autopsy showed the intestinal lesions of typhoid fever. The necrobiotic changes in the liver were more pronounced than are usually found in similar cases of typhoid in normal individuals. (Dr. Packard asks whether cretinism may not diminish vital resistance.) Of special interest in the case was the marked calcification of the arteries of the thyroid gland and the increase in the size of the posterior lobe of the pituitary body; this posterior lobe, moreover, resembled the anterior in structure, a condition which other observers have likewise noticed. The epithelial cells in the thyroid gland were abundant but varied greatly in size and the alveoli were marked off distinctly by fibrous tissue. Colloid was relatively deficient; where not wholly absent the masses were small. The changes found in other organs were such as might be attributed to the fatal febrile affection rather than to cretinism. In the skin, however, lymphoid infiltration of the corium was noted; islets of lymphoid tissue were found, especially around the ducts of the sweat glands. Possibly this localization was due to the excessive action of the sweat glands caused by the administration of thyroid extract.

Peculiarity in Hands of Degenerate Children.—Dr. Koplik presented to the Society two casts of hands in dwarfs—one of them a cretin, the other an idiot but not a cretin. Attention was called to a peculiar prominence over the pisiform bone. Dr. Koplik first noticed this in cretins, but further investigation, in conjunction with Dr. I. Lichtenstein, showed that the same peculiarity exists in other types of degenerate children. The prominence is adjacent to the groove which separates the hand from the forearm; it is an abrupt eminence, which viewed from the side gives a bayonet-like appearance. A first impression was that it was due to hypertrophy in consequence of prolonged crawling on the floor; it has been seen, however, in a cretin three months old. It occurs in idiots, cretins, microcephalis. In patients presenting the appearance of cretins but having normal intelligence, this sign is absent. Dr. Koplik regards the condition as a true stigma of cretinism.

Vital Resistance in Cretins under Treatment.—Dr. W. S. Christopher saw a case of cretinism which developed tuberculosis in the course of treatment and was rapidly carried off. He has noticed frequently an elevation of temperature in patients under thyroid treatment; furthermore these children suffer much from disturbed sleep. When more than 2 grains of thyroid extract is used daily there is a marked increase in the urates eliminated and a tendency to the formation of uratic deposits.

Dr. J. Park West began the treatment of a cretin fifteen months ago; after six weeks of treatment severe bronchitis developed and was very badly borne; only the most careful nursing pulled the patient through the attack. The case reported by Dr. West several years ago has successfully passed through measles and is very hardy.

Dr. A. C. Cotton noticed in two cases that as the cretin characteristics disappeared the powers of resistance waned; both cases developed influenza, experimentally that with the

larger doses the rise in temperature seemed exactly to correspond with the dose given. Minimum doses being resumed, temperature became normal.

Early Improvement Under Thyroid Treatment Is Not Maintained.—The rate of improvement, according to Dr. Christopher, is a diminishing one. The patients rapidly improve at first; then betterment ceases. Dr. Northrup concurs in Dr. Christopher's view. Much depends, however, on how soon the patient begins treatment; if the administration of thyroid can be begun under one year of age the results are marvelous.

Dr. Christopher saw two colored cretins—brother and sister, the former twenty-one years old, the latter younger. The boy refused treatment; the girl accepted it and grew somewhat better. Two of the most successful cases treated by Dr. Christopher began to take thyroid between 4 and 5 years of age.

(To be Continued.)

NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY.

First Annual Meeting Held in Washington, May 14, 15, 1901.

The President, the Hon. William Pryor Letchworth, LL.D., in the Chair.

Epileptics in Foreign Countries.—A number of communications from distinguished foreign authorities were read, Professor Paul Kovalevsky, St. Petersburg, giving an account of epileptics in Russia; Professor Jules Morel of Mons, Belgium, sending a report from that country; Professor F. Kalle and Dr. T. Kalle giving accounts of the steps that have been taken for dealing with the disease in Switzerland; Professor Oskar Medin, of the Karolinska Institute, describing the conditions that prevail in Sweden; Dr. S. C. Zavitiano, president of the Imperial Society of Constantinople making a report relative to epilepsy in Turkey; Pastor Siebold on the work that is being done at Bielefield in Germany; Professor C. Mangazzini, of Rome, on the care and treatment of epileptics in Italy; Dr. Horelburg, medical deputy of the consul general in Rio de Janeiro, on the prevalence and treatment of the disease in Brazil; Dr. Secundino E. Sosa on the provisions that are being made in Mexico for the treatment of epileptics; and Mr. G. P. Gaskell, London, on the work of the recently formed National British Society for the Employment of Epileptics.

While some of the reports showed an awakening of public opinion to the necessity of adopting more systematic steps for dealing with the disease, all concurred in acknowledging the credit which was due to the United States for taking the practical lead in regard to the provision of cottage colonies and villages for the care and treatment of epileptics. In the Swedish report mention was made of the fact that a law forbidding the marriage of epileptics has existed in Sweden for over a hundred and fifty years. The report from England showed that the society which has been formed there for the purpose of assisting epileptics capable of doing certain kinds of work has met with a gratifying amount of success.

Care of Epileptics in the United States.—The most interesting papers regarding the work being done in the United States were those by Dr. Frederick Peterson, of New York, the new President of the State Board of Lunacy, and Dr. William P. Spratling, superintendent of the Craig Colony for Epileptics at Sonyea, this State. Dr. Peterson traced the history of the disease from the earliest times, quoting what Hippocrates said as to its origin and nature, and also some lines from Lucretius which he regarded as giving a particularly good clinical picture of an epileptic seizure. Dr. Spratling's paper gave a detailed account of the treatment relied on at Craig Colony, which consists of giving the colonists congenial occupation, as far as possible in the open air, regulating their diet and habits of life, and only having recourse to bromides and other drugs at severe stages of the disease. Incidentally it was mentioned that the Craig Colony has received a sufficiently large appropriation this year to provide for about two hundred additional patients. When the new buildings which have been planned are completed, the colony will have facilities for more than a thousand patients. Dr. W. N. Bullard, Boston, described the progress which has been made with the establishment of the Massachusetts State Hospital for Epileptics. Dr. Wharton Sinkler gave an account of special provisions which have been made for epileptics in Pennsylvania. General Brinkerhoff, member of the Ohio State Board of Charities, spoke of the difficulties which had been encountered in that State by those who had interested themselves in the provision of a separate institution for the care of epileptics, and of the measure of success which had ultimately crowned their efforts. The New Jersey Village for Epileptics was described by its superintendent, Dr. H. M. Week, whilst statements on the condition of epileptics in Connecticut, Illinois, Texas, Virginia and North Carolina were made respectively by Dr. Edwin A. Down, Hartford; Miss Lathrop, Chicago; Dr. B. M. Worsham, Texas; Dr. William F. Drury, Petersburg, Va.; and Mr. C. B. Denson, Raleigh, N. C.

In the course of general discussion, Dr. G. H. Knight, of Lakeville, Conn., said he thought the steps that had been taken by New York, Ohio and other States were steps in the right direction, and even if they did not succeed in curing a single case, they would assuredly do a great deal in the way of checking the spread of the disease. His experience with feeble-minded children and examination into

their histories had proved that epilepsy was one of the leading causes in the production of offspring with mental deficiencies. There was a law in Connecticut forbidding the marriage of epileptics and the feeble-minded, and while there were persons who raised questions about the interference with personal rights which this involved, he did not think there was any room for such objections in so far as those who had become wards of the State were concerned. A small percentage of cases, those namely that were not wards of the State, were in a different position. If the increase of feeble-minded children was going to keep on increasing as it was doing, it would be found necessary to do something beyond the taking care and teaching of these classes. It would be necessary to stop the increase, for he did not believe that civilization could stand the inroads thus being made on it. Replying to the chairman, the speaker said he found only a very small percentage of cases of feeble-mindedness directly traceable to alcohol on the part of the parents.

Etiology of Epilepsy.—Dr. Robert H. Porter of Chicago, said he proposed reading a paper at the A. M. A. meeting at St. Paul supporting the old theory that epilepsy was due to the deterioration of the nerve cells and tissues of the brain and spinal column. It might indeed be said that impairment of the nutrition of the nerve cells was the common cause of epilepsy, idiocy and feeble-mindedness. This led to congestion of the brain, which was the immediate cause of the paroxysms. He had been studying problems connected with epilepsy for twenty years, and he was prepared to argue that the disease could be arrested and the patient cured. It was well known that remedies that stimulated the abdominal secretions helped to divert the brain circulation and if this could be done the spasms could be controlled. Later on in the proceedings the speaker exhibited a patient who, he contended, had been practically cured of epilepsy.

General Treatment.—Dr. William A. Polglase, superintendent of the Michigan Home for the Feeble-minded and Epileptics, said he had not much to add to the discussion of this phase of the subject. He had long been looking for such a plan of treatment as had just been described, and would like to know more about it. Personally he was unable to offer one single thing in treatment looking to cure. They were all agreed as to the general treatment both for relieving the spasms and alleviating the condition of the patients, but beyond that he was not prepared to go. He was not even prepared to say that in every case there was a disturbance of the cells in the center of the nervous system. Recently he thought he had struck upon a plan for the treatment of all epileptics, but he had an influx of thirty or forty patients, and the result of his experiments was to upset all his theories. The main difficulty with which they had to contend was that there were so many different kinds of the disease, with innumerable other cases that simulated it. He would strongly advise epileptic persons not to marry, and indeed would favor a law to prevent the union of all neurotics.

Epilepsy and Marriage.—Dr. W. N. Bullard, president of the Board of Managers of the Massachusetts State Hospital for Epileptics, remarked that before they discussed the subject in its relation to marriage it was desirable to know exactly what they were discussing. There were a great many different degrees of epilepsy. There were persons who had an attack only once a year or so, and many of these were extremely able persons—men who managed large industrial concerns, lawyers, literary men and others; and there were all kinds of patients downwards from these to the insane. In considering the desirableness of prohibiting marriage they must decide what class they were dealing with. Epilepsy again was a disease or a condition of the nervous system which might be produced by a variety of causes. It might be hereditary, or it might be produced by an injury. Therefore it might be necessary to consider whether the disease was of a kind that was likely to be transmitted to the offspring of the sufferer. One thing he had noticed was that there were many cases in which the disease commenced very early in children and yet no trace of hereditary origin could be found. On all these grounds he thought it essential that they should proceed very slowly and define very clearly what classes of cases should be prohibited from marrying.

Mr. Mack of Sandusky, Ohio, called attention to the law which had been passed in Minnesota to prevent the marriage of the mentally unfit.

Dr. James M. Murdoch of Polk, Pa., said his experience was confined to institutions for the care of the feeble-minded. Large numbers of epileptics, however, came to the institution with which he was connected, and he found that they were benefited by careful diet and regulation of the secretions. The diet consisted largely of farinaceous foods, and it was found necessary to prevent tendencies to gluttony.

Dr. Down of Hartford, Conn., spoke of the different theories that existed as to the etiology of epilepsy, and the difficulty of collecting statistics and making proper classifications of sufferers from the disease. Replying to a question put by Dr. Spratling, the speaker said that it was found in Connecticut that a large proportion of the epileptics were foreign born.

Clinical Groups.—Dr. Spratling said he had been engaged in special work among epileptics for fifteen years, and he had been particularly struck by the different developments that the disease took. If neurologists ceased making

attempts to define the disease he thought it would make their works more valuable. There were many theories as to the cause or causes of epilepsy and plenty of data to support each of them, and yet none of them that could be entirely reconciled with each other. He approved of the prohibition of the marriage of epileptics, and maintained that the whole question of the proper way of providing for them should be dealt with by the national government.

Epilepsy among Negroes.—Mr. Denson of Raleigh, N. C., in speaking of epilepsy among the colored population, said that before the war, while negroes with fits were plentiful, the insane negro, that was the negro affected with anything like acute mania, was practically unknown. He did not know whether the fact that the latter had become common since was evidence of degeneration, or was to be accounted for by the circumstance that the negroes felt the slings and arrows of outrageous fortune in a way that they did not do when they had a protecting arm over them.

Dr. Wharton Sinkler, describing his experiences in Pennsylvania, dwelt on the necessity of having institutions exclusively for the care of epileptics instead of leaving them to be attended to in workhouses and hospitals for the insane.

New Office-Bearers.—The election of office-bearers for the current year resulted as follows: President, Dr. Frederick Peterson, New York; vice-presidents, the Hon. William Pryor Letchworth, Portage, N. Y., and Professor William Osler, Baltimore, Md.; secretary, Dr. William P. Spratling, Sonyea, N. Y.; treasurer, Dr. H. C. Rutter, superintendent Ohio Hospital for Epileptics, Gallipolis, Ohio.

The objects of the Association are: (1) to promote the general welfare of sufferers from epilepsy; (2) to stimulate the study of the causes and methods of cure of this disease; (3) to assist the various States in America in establishing a uniform system of care for epileptics; and (4) to advocate the care of epileptics in institutions designed for their special needs, where they may (*a*) receive a common school education, (*b*) acquire trades, and (*c*) be treated by the best medical skill for their malady.

NEW YORK ACADEMY OF MEDICINE—SECTION ON MEDICINE.

Stated Meeting, Held Tuesday, April 16, 1901.

E. Franklin Smith, M.D., Chairman.

Accurate Percussion Method.—Dr. George M. Converse read a paper in which he brought out a simple and accurate method of percussion of the heart, as practised by the late distinguished Professor Potain of Paris. He said that the distinctive features of the method were the use of the finger and not of Sansom's pleximeter, nor of any other form of instrument. The percussion is formed not by a series of successive strokes, but by a single stroke of moderate force and then a pause until the significance of the sound elicited can be thoroughly appreciated. The finger, as a pleximeter, is better than any instrument because it enables the examiner to judge of the consistency of the tissues below his finger and the resistance offered by them. The method of the single stroke saves the patient pain.

Alteration of Pitch.—Dr. Converse said that the alteration of pitch is much more important for the determination of the size of the heart than the occurrence of distinct dulness. This method enables the prognosis of heart lesions to be given with much more assurance than usual. In one case when the patient came under treatment the outline of heart dulness enclosed an area of about 104 c.m. Later on percussion showed an area embracing 169 square cm. The case was one of aortic regurgitation and this increase in area showed that dilation was rapidly overcoming the influence of hypertrophy in heart compensation and that the prognosis was distinctly unfavorable.

Postmortem Verification.—In eight cases Dr. Converse has had the opportunity to verify his findings. The outlines of the heart dulness and of the sternum and the suprasternal notch and both nipples were marked on the chest wall. Over this a piece of transparent paper was placed and the outlines transferred to this. After the death of the patient, this was replaced on the chest, and various parts of the outlines marked by piercing the chest walls with large pins. In all of the eight cases the outline of dulness, as determined by percussion, represented the actual outlines of the heart beneath the chest wall.

Percussion in Deep Chests.—Dr. Judson Daland said in discussion that the points of Potain's method which are especially useful are the single stroke of the finger and the appreciation of the difference in pitch between two successive strokes, and then the looking for shades of difference in pitch rather than distinct progress from resonance to actual dulness. These points, of course, are not entirely due to Potain, but are in use by most accurate diagnosticians. In the ordinary normal chest, it is not difficult, as a rule, to map out accurately the area of the heart. In deep chests, however, with a long antero-posterior diameter, the difficulty becomes very marked. Even before true emphysema exists, this difficulty adds very greatly to the indefiniteness of percussion investigation.

Auscultatory Percussion.—Dr. A. H. Smith said that for accurate diagnosis, especially in cases with precordial tenderness, the method of auscultatory percussion is extremely helpful. There is a notable distinction in the dulness of different organs furnished by this method. There is a distinct quality of liver dulness that differentiates it easily from heart dulness. It is possible to separate the outlines of liver and heart dulness very accurately.

Arterial Spasm and Heart Dilatation.—Dr. Judson Daland of Philadelphia read a paper on a case which seems to illustrate very clearly the effect of arterial spasm in producing dilatation of the left heart. The patient is a girl, ten years of age, who had been robust and vigorous. She had suffered from measles and diphtheria, but none of the other diseases of childhood. She had never had any heart trouble, nor suffered from chorea, nor rheumatism, nor growing pains. Some time before she came under observation she had been bitten by a cat. The wound healed slowly, but was completely healed after about three weeks. About seven weeks after the cat bite, she came to the dispensary of the University of Pennsylvania, complaining of pains in the head and back. At first it was thought that there had been some slight septic condition. The true cause of the symptom was that the child had the habit of taking a certain table sauce in excess. She was also very fond of salt and ate it to excess. She had an older sister who indulged in the same peculiar taste. Both of them preferred to eat oranges with salt rather than with sugar. Because of their fondness for it the mother had given up putting the sauce on the table, but bought a bottle at Christmas-time. The child poured three ounces of the sauce into a cup and ate it on bread. Very shortly afterward she was taken with pains in the epigastrium, there was some vomiting and diarrhea and there was severe thirst and some symptoms of collapse. For some time afterward she suffered from insomnia. About a week later, she took another dose of the sauce and this proved even more severe in its effect. The child had two convulsions in each of which she was unconscious and they were marked by opisthotonus. After the convulsions there was a period of coma followed by long, deep sleep. Some days after this an anasarcous condition developed. When she was brought to the clinic she had a temperature of 99.5° F. and a pulse of 110, the specific gravity of her urine was 130 and one-fourth of it, by bulk, consisted of albumin.

Heart Symptoms.—The second sound at the aortic cartilage was very much accentuated, there was a systolic murmur at the apex that was transmitted into the axilla and could be distinctly heard. The apex beat was distinctly lower and to the left of its normal position. The radial artery felt like a wire. It was thin, but hard. When the pulse was obliterated by pressure, the arterial walls could still be felt, showing that they were thickened. The symptoms were those of hypertrophy, but the conclusion reached was that the condition was one of acute dilatation.

Effects of Treatment.—Under rest, with an absolute milk diet and the free administration of Basham's mixture, improvement began almost at once. The edematous condition gradually disappeared and a distinct diminution in the force and area of the apex beat could be noticed from day to day. Finally the apex beat came to occupy its normal position again. When the patient came into the hospital, she was passing only about twenty ounces of urine a day, containing a large proportion of albumin. When at the end of about three weeks, she was discharged she was passing from twenty five to thirty ounces a day and all the symptoms had disappeared.

Cayenne Pepper as the Toxic Factor.—A detailed analysis of the sauce was not obtained, but it is known to contain a large amount of Cayenne pepper and certain other strong spices. The original symptoms point to the existence of an acute catarrhal gastritis with the absorption of toxic material from the intestines. These led to an extreme congestion of the kidneys. As a result of this congestion some uremic symptoms developed. The toxins in the blood acted locally on the blood vessels and on the lining of the heart, causing intense irritation and some local thickening. The irritated and thickened arteries were especially liable to take on a spasmodic condition. The spasm of the arteries led to dilatation of the left ventricle and the murmur was due to this dilatation. When the left ventricle is dilated the capillary muscles are displaced from their usual position, they do not act simultaneously and this failure of consentaneity leaves a chink or space in the leaflets of the valve. This causes leakage and explains the temporary murmur.

Mitral Leakage Conservative.—This mitral leakage is really a conservative effort on Nature's part. It relieves the strain on the left ventricle, which in its dilated condition and acting against spasm in the arteries would be unable to empty itself by contraction only for the relief afforded by the opening at the mitral valve. This is really Nature's incipient compensation for the mechanical difficulties against which the heart has to work.

High Pulse in Scarlatina.—In discussion Dr. William H. Thomson said that Dr. Daland's communication was of interest from many standpoints. There seems no doubt that in certain infectious diseases, as, for instance, scarlet fever and rheumatism, complete acute dilatation of the heart depends at times on spams of the arteries. That this spasm exists there is no doubt. A high tension pulse is one of the best diagnostic signs of scarlet fever. When called to see a child suddenly wakened from its sleep with some vomiting, a high fever, slight sore throat, the presence of a small artery with high tension, one may consider these symptoms almost pathognomonic of scarlet fever. This small contracted artery may help to the acute dilatation.

Internal Arterial Spasm.—Dr. Thomson called attention to the fact that at times when there is no spasm of the external palpable arteries, there may be spasm of internal arteries especially in the splanchnic region. It is evident that in many cases some sort of vasomotor storm in the splanchnic area leads to spasm of the arterioles and so interferes with the normal course of elimination.

Atheroma Without Hypertrophy.—There have been a number of cases reported now in which extensive atheroma of arteries existed without the development of hypertrophy of the heart. This means that there is no necessary connection between the two pathological conditions. It would seem that too much stress has been laid on the physical factor in the production of cardiac hypertrophy. The mere fact of the arteries losing their elasticity is not enough to cause the heart to hypertrophy. At an insane asylum in England, 194 cases of atheromatous arteries were reported, in only four of which hypertrophy of the heart existed. On the other hand in the autopsies at Charing Cross Hospital 80 per cent. of the cases with atheromatous arteries have heart hypertrophy. The difference between the lives of the two classes of patients indicates at once the reason for this. Nearly all the admissions at Charing Cross Hospital are of working people. Heart hypertrophy is due to strain. Strain also produces arterio-capillary fibrosis. Atheroma develops especially on the parts of the arteries where the strain is greatest—on the outer portion of the arch of the aorta, for instance, and where arteries branch and so are subjected to special strain. The artery in the body which is most liable to atheroma is the one most subjected to muscular influences. This is the anterior tibia. On the other hand the pulmonary artery is very rarely atheromatous and never except when there is mitral stenosis. The question of the exact point in the arterial system at which the strain originates has long been under discussion. The arteries are especially affected. Their muscular coats are marked by increase in size and sclerotic conditions easily develop in them. It is clear, then, that the source of the strain is at some point beyond the arteries. It undoubtedly exists in the capillaries. The network of minute vessels connecting veins and arteries is especially liable to be affected by toxins and the minuteness of the vessels enables them to add greatly to the circulatory tension, when affected sufficiently, to become spasmodically contracted. Thoma showed experimentally on recent dead bodies that the arteries would stand considerable pressure. He was able to inject seventeen liters of salt solution before the exudation of fluid into the tissues. Where atheromatous conditions existed, however, four liters of salt solution were sufficient to produce edema. The normal resisting power of the arterial system was thus reduced to one-fourth its capacity.

Cause of Capillary Resistance.—The primary cause of the rise in blood pressure which is due to the capillary resistance is some toxin substance in the circulation which interferes with the normal osmotic changes between the blood and the extravascular fluid. Syphilis, alcoholism, plumbism and the poisons of the infectious diseases act on the interior of the capillaries, rather than directly on the larger blood-vessels.

Treatment of Incipient Canillary Fibrosis.—The great remedy for the neutralization of these toxic substances in the blood is undoubtedly oxygen. The conditions that finally lead up to fatal degeneration in the circulatory system can be modified favorably by oxidation. For these cases the best antitoxin is fresh air, day and night. Nothing better than this can be advised and no method of drug treatment can replace it.

Angina Without Lesions.—Dr. Beverley Robinson said that, as a rule, when angina pectoris is considered, spasm of arteries is thought of and the paroxysms of the disease are attributed to a spasm of the coronary arteries with ischemia of parts of the heart wall. There are certain cases, however, in which death takes place sometimes after a series of well-marked attacks of angina pectoris, sometimes after a single attack in which the sclerotic condition of the coronary arteries is thought to exist, and yet at autopsy none is found. No reason for death can be found in some of these cases. They remind one of another series of cases in which what is probably an ischemic condition of cerebral centers simulates apoplexy. The diagnosis of apoplexy may even be made. Death may occur and at autopsy nothing in the shape of a definite hemorrhage be found. The only conclusion in such cases is that the apoplectic condition is due to spasm of the cerebral arteries.

Causes not Physical.—The physical factors that produce heart disease have been deemed too important, and it is not realized that a large number of chemical and biological factors enter into the problem. The assumption that more is known about heart disease than is really the case had led to a good deal of credulousness as to specific cures for heart troubles. There seems no good reason to think that Nauheim, for instance, possesses any specific for heart trouble and yet cases are benefited after failure to find relief under other treatment. Suggestion plays an important rôle in these cases and, undoubtedly, sometimes where lesions are supposed to exist, there is only some passing condition that an improvement of the general system help very materially.

Myocardial Degeneration.—Dr. M. Manges said that high tension due to spasm in the arterial system undoubtedly is a very important factor in the production of myocardial heart dilatation. It must not be forgotten, however, that this dilatation is helped on by myocardial changes which are produced by the toxins of the infectious diseases, or by other toxic substances that occur in the blood. Just as the coats of the arteries are affected, and among them the muscular coat, so the inner lining of the heart and the myocardium is affected. Besides this the arteries of the heart themselves are affected and this produces myocardial changes. When the heart vessels are not affected changes in the heart are infrequent. Arteriosclerosis is almost invariably toxic in origin and is not merely due to physical factors. Schroeter showed by weighing

the heart and sections of the heart that often, and when extensive arteriosclerosis existed, there was no hypertrophy either of the whole heart nor of parts of it.

Unity of Circulatory System.—Dr. Andrew H. Smith said that the arterial tree must not be thought of as something distinct from the heart, but as really a continuation of the heart. Every part of the arterial system has a muscular coat and this acts continuously and successively in the production of the blood flow. The contraction begins in the auricle, continues to the ventricle, and spreads from there to the aorta and its branches down to the smallest of them. Every bit of this contraction requires the exercise of nervous power. The question of arterial spasm takes on a new aspect because of the changes taking place in the myocardium, because they are taking place in other parts of the arterial system and all of these parts are joined not only by sympathy and physical factors, but by continuity of structure and community of function.

Sphygmographic Tracings.—Dr. Van Santvort said that the sphymogram, when properly used, enables one to recognize changes in blood-pressure that would otherwise remain unknown. The second sound, although often spoken of, is no index of arterial tension, or of the strength of heart contraction. In pneumonia the second sound is often strong out of all proportion to the normal, but is not a sign of heart force, but of difference of pressure on the two sides of the heart valves.

Evidence from Single Case.—In closing the discussion Dr. Judson Daland said that the reason for giving the case he had described in so much detail was that it seemed to set forth the problem of heart dilatation in its simplest terms. The arterial affection was due to a simple toxic substance and not to the complicated conditions which exist in infectious diseases. It occurred in a child in whom the wear and tear of the arterial system had been very little and who had been reasonably robust before the illness. The case also seemed to throw light on the occurrence of uremia. Uremic symptoms differ in every case and undoubtely the poisons which caused the symptoms were very different in different patients. This case seems to emphasize the fact that there is a marked difference between the effect of inflammatory vascular changes and pure dynamic changes. Undoubtedly Dr. Thompson's observations, which seem to point to internal arterial spasms, will be confined and will throw light on the origin of various heart symptoms. The obstruction which produces high tension in the circulation seems undoubtedly to be situated in the capillaries.

Long Island Climate.—Dr. LeGrand N. Denslow said that the nearest true maritime climate in New York is situated on the eastern part of Long Island. A series of observations has shown him that the climate of this part of the island is less liable to change, is warmer in winter and cooler in summer, and has more sunny days than almost any other part of the United States and than any place along the Atlantic Coast. It seems sure that at times heat from the Gulf Stream is carried to Long Island and modifies the weather. The mean summer temperature is that of northern New York. The mean winter temperature is between that of New York and Washigton. The ocean retards the progress of the seasons and hence there are less sudden changes of temperature. There is less range of daily temperature and the midday heat is tempered by an ocean breeze. The south is particularly favored in this way. The hills and timberland lying back of this southern shore protect it very well in the winter time. Block Island represents the eastern end of Long Island very well. According to the Government Reports there is less range of temperature on Block Island than almost anywhere else in the country. There are only seven degrees of difference between day and night. The first frost on the eastern end of the Island comes later by three weeks than in New York City. It is wonderful what a number of sunshiny days there are in eastern Long Island. Near the ocean one would almost naturally expect rather cloudy, dark weather. As a matter of fact the eastern and southern shore of Long Island compare very favorably with the most sunny parts of the United States. There are 100 more sunny days than in New York City, and 150 more than in north central New York, at Rochester, for example. It is a matter for surprise that this state of weather affairs should exist. It is hard to account for it. But the fact remains that the eastern end of long Island makes an exceedingly favorable climate for invalids. At a distance of only three hours from New York there is a very favorable place for patients suffering from tuberculosis, or from heart, or kidney trouble. While we hesitate to send people to distant parts of the country there need be no hesitation to advise residence at so short a distance from home.

BOOK REVIEWS.

A Manual of Practical Hygiene for Students, Physicians and Medical Officers. By Charles Harrington, M.D., Assistant Professor of Hygiene in the Medical School of Harvard University. Lea Brothers & Co., Philadelphia and New York.

In the great annual output of medical works it is a rare thing to find one that startles the prosaic reviewer into enthusiasm. It was given to Huxley to write science as literature, and something of that same vivifying touch of realism and interest in actualities is found in the pages of Dr. Harrington's Manual.

It is impossible to dip here and there in the

volume, one is fascinated into steady reading, and is made aware of the touch of a man who knows his facts at first hand from personal observation, and who has not compiled them from other text-books. There is moreover none of the musty laboratory atmosphere that obscures rather than enlightens, so prevalent in other works on hygiene. We miss, with a sense of relief, the endless technical bacteriological discussions and the pages of statistical tables which form so large a part of the scholastic treatises on this subject.

Foods, Air, the Soil, Water, Habitations, Sewage and Garbage Disposal, Disinfectants and Disinfection, Quarantine, Military Hygiene, Naval and Marine Hygiene and Tropical Hygiene, Hygiene of Occupation, Vital Statistics, Personal Hygiene, Vaccination and Disposal of the Dead are the subjects treated.

In all of the chapters the author has gone directly into the heart of the subject-matter, and as a consequence there is no padding in the work. It is all solid material. We congratulate the author on giving such an excellent manual and recommend it cordially to our circle of readers. We desire moreover to suggest that because of its simple and straightforward style no better book could be recommended by a physician to his patients who have a leaning toward acquiring that "knowledge" which is a "dangerous thing" from other sources not so trustworthy.

A Treatise on Mental Diseases. Based upon the lecture course at the Johns Hopkins University, 1899, and designed for the use of practitioners and students of medicine. By Henry J. Berkley, M.D., Clinical Professor of Psychiatry at the Johns Hopkins University, Chief Visiting Physician to the City Insane Asylum, Baltimore. D. Appleton & Company, New York.

The prefatory note to this book begins with the following sentence: "The absence from English medical literature of a comprehensive, practical work on mental diseases—one adapted to the needs of the busy practitioner as well as to those of the student of psychiatry—has led the writer to prepare this treatise embodying a consideration of all the principal forms of psychical disturbance." This statement is not justified in the least and it is a pity that such an excellent presentation should, at the outset, imply such an aspersion on English and American psychiatry. That Dr. Berkley has given us the best modern English treatise we gladly admit, but the problems of psychical disturbance have been written on by others both "practically" and "comprehensively." There is, we believe, no domain in medicine which is capable of receiving so many different interpretations and it is to the author's credit that he has been able to arrange and epitomize, and at the same time to bring some order into the chaos of modern German psychological psychiatry.

The [illegible] has many excellent points. It is, we believe, almost alone in its complete study of morbid anatomy, as revealed by the histological technic of the last decade, thus supplementing Bevan Lewis' excellent treatise. The characterization of the clinical types of insanity is extremely well done and forms an important contribution to American psychiatric literature. We confess to a certain sense of being adrift on this modern sea with so many of the familiar landmarks ruthlessly destroyed, yet out of the new order of things a closer grasp of vital principles is inevitable.

One of the most striking parts of the book is the statement with regard to the unfavorable prognosis of most mental diseases. When Kraepelin stated that among 1,000 cases of acute mania he had observed only one in which the symptoms did not recur, most psychiatrists were inclined to doubt the value of his statistics. Now that the discussion of the subject has been carried on for some time, Berkley is in a position to announce the conclusions generally accepted in the matter. Simple mania, he says, is an exceedingly rare form of mental disease and therefore, one should be cautious in making a prognosis of final recovery. Relapses after a number of years, when stability is apparently assured, are frequent, as every one interested in mental medicine knows only too well. With regard to melancholia he says, "Relapses in this form of mental disease are very common, perhaps one-half of those affected falling back at some period, from a few weeks to years."

Professor Berkley's remarks on treatment are especially complete and practical. Many of his therapeutic hints are the result of his own experience.

The Optician's Manual. A Treatise on the Science and Practice of Optics. By C. H. Brown, M.D., Graduate of the University of Pennsylvania; Professor of Optics and Refraction, etc., etc. The Keystone, Philadelphia, Pa.

Fourth edition in four years is evidence the book fills its own place. Careful reading of this shapely, readable manual shows that it is couched in language plain and intelligible. No attempt is made to be scholarly. The aim is instruction by means of the simplest language that will convey it elegantly. The author lucidly treats all the necessary matters pertaining to the optician's complete equipment. In his chapter on "Outfit Required," other books of allied nature are named, which, if all are carefully read, will carry the reader beyond the merely practical and elementary into a more or less masterful acquaintance with these subjects. This applies especially to the scientific work of Dr. M. Tscherning. It was a thoughtful thing to append the glossary But it is to be hoped those who could read this book with interest and a desire to master it and read its congeners, would desire to have a larger dictionary of terms than this and a fuller consideration of them. But the book reads well and accomplishes its aim, which is high praise.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVIII. NEW YORK, SATURDAY, JUNE 8, 1901. NO. 23.

ADDRESSES.

THE PRESIDENT'S ADDRESS.[1]

BY CHARLES A. L. REED, A.M., M.D.,
OF CINCINNATI, OHIO.

In approaching the discharge of my duties as presiding officer of the fifty-second session of the American Medical Association, I beg to express my appreciation of the generous suffrages by which I have been called to a position of such conspicuous honor. This appreciation becomes all the more pronounced when I reflect upon the magnitude and achievements of this great national body and upon the luster of the distinguished men who have presided over its deliberations. This thought brings me to the first duty of the occasion, and that is, officially to bring to your attention the fact that since our last reunion three of my most illustrious predecessors have been called from their worldly activities to the realm of rewards—Alfred Stillé, Lewis A. Sayre and Hunter McGuire, each a former President of the Association, died within a single week. Their lives were known of men, their records are ornaments of our annals, and their achievements are their eulogies. They labored zealously and with beneficent results, not alone in the scientific field, but in behalf of an organized national profession; and to guard zealously the splendid legacy which they, among others, have left us, must be one object of our labors upon this auspicious occasion. The hope is indulged that steps may be taken to procure suitable portraits of these and of other deceased Presidents of the Association, to be placed in some safe gallery until such time as the Association may be able to transfer them to its own Temple of Fame. I recommend that suitable formal action be taken on this occasion relative to the life, distinguished services, and the death of these lamented *confrères*.

Foreign Relations of the American Medical Association.—The American Medical Association accredited delegates during the last year to several foreign medical conventions, notably the International Medical Congress at Paris, the Dominion Medical Association of Canada, the Mexican National Association and the Pan-American Medical Congress at Havana. To each of these organizations the American Medical Association sustains relations of peculiar intimacy. As one of the great scientific nations of the earth, the United States is naturally an integral part of the International Medical Congress. This Association, by a resolution presented by your present executive officer took the initiative in 1891, in organizing the Pan-American Medical Congress. The first reunion of that Congress was held in Washington in 1893, under the presidency of the late lamented Dr. William Pepper.

Fiscal Affairs and the Journal.—It has passed into unwritten law, born of the gradually developing features of our organization, that your President shall restrict his annual address to a discussion of the affairs of the Association and to the great object to which, by the terms of its Constitution, it stands consecrated—"the common interests of the medical profession in every part of the United States." In compliance with this rule, and realizing that I am leaving scientific questions to be presented by orators appointed for that purpose, I have pleasure in calling your attention to the satisfactory condition of the affairs of the Association, as indicated by consolidated report of the Treasurer of the Board of Trustees. From it you will observe that under the judicious management of your Board of Trustees you had a cash balance at the end of the last fiscal year of $31,004.67, being an excess of $3,696.66 over the preceding year. Your plant has been increased in value to the amount of nearly $10,000.00, and the net profits of the *The Journal* amounted to nearly $14,000.00. You will be gratified to realize that, in addition, you have safely invested as part of a fund with which to buy a home for *The Journal* and for the Association, the respectable sum of $25,000.00. If, however, you have occasion to feel satisfied with the normal condition of your finances, you must contemplate with pride the rapid increase of your *Journal*, in quality, size, circulation and influence. The average weekly circulation grew, during the last fiscal year from 13,672 to 17,446, and I have added pleasure in informing you that, since the period covered by the report, the weekly circulation has grown to 22,000 copies. For the accomplishment of these splendid results, I feel that you will join me in hearty acknowledgment, not only of the sagacious management by the Board of Trustees, but the tireless industry and the discreet direction of our accomplished editor, Dr. George H. Simmons.

Scientific Work of the Association.—It must be acknowledged that great as has been the progress in this particular, too much of the time of our general sessions is yet devoted to the consideration of matters which might, with propriety, be relegated for final action to a similar body. It would redound largely to the interest of our annual session if the general membership could be entertained and instructed at our general meetings by exercises of a more purely scientific character, of such broad nature that they should not be re-

[1] Abstract of President's Address, delivered at the Fifty-second Annual Meeting of the American Medical Association, held at St. Paul, Minn., June 4-7, 1901.

stricted to any of the sections. A reform in this particular will be a long step in the direction of progress.

Congressional and State Legislative Affairs.—The American Medical Association, during the first fifty years of its existence, exerted relatively little influence upon legislation, either state or national. Since the Standing Committee on National Legislation and the National Legislative Council of delegates from the state societies have been established, and have become coöperative, there is some evidence that the voice of the profession is heeded at Washington. The experience of the splendid committee of the Association, acting in concert with the National Legislative Council during the last year, has, however, shown the serious necessity for more thorough organization in protecting the interests of the profession, and the interests of society as represented through the profession. In every war known to history the deaths from preventable diseases have exceeded those due to battle. At no time has hygienic science been so resourceful as at present in preventing disease. A law which fails to give to armies, either in peace or in war, the fullest protection by the application of the latest scientific developments at the hands of specially trained medical men is unjust to the soldier, to society, and to the medical profession. In view of these facts, the army reorganization law of the last Congress was inexplicable and inexcusable. The cause of failure on the part of this Association to procure legislation by the Congress—and with the exception of preventing the passage of the Antivivisection bill last year and securing the enactment of the Quarantine bill this year, our recent efforts must be recognized as failures—I say the causes of our failure are properly subjects for careful consideration. I have examined the records of the Association from the date of its organization, and have been profoundly impressed with the fact that memorials, resolutions, or even more definite propositions addressed to the Congress have, for the most part, represented the views, or rather the impressions, of the individual members proposing them. In view of the fact that, after all, the argument of votes is the only one which appeals effectively to the average Congressman, it behooves this Association, in its efforts to conserve the interests of the profession and of society, to put itself in position to influence the largest number of votes. Every physician, therefore, should, in a perfectly respectable sense, become an active working politician. This subject, however, is of such breadth and of such depth that it may be well for us to pause at this juncture long enough to consider from the standpoint of fundamental facts, the relationship of physicians to each other, and of the medical profession in the aggregate as an integral factor in society.

Voluntary Regulations of Medical Practice.—A half century ago the American Medical Association was organized with the avowed object of having its members represent and take cognizance of "the common interest of the medical profession in every part of the United States." It sought to cultivate medical knowledge among its members, to elevate the standard of medical education, to promote the honor and influence and interests of the medical profession, and to enlighten the public concerning the relation between the medical profession and society. Emulation and concert of action in the profession and friendly intercourse among those engaged in it were additional aims of the founders of this great body of representative American medical practitioners. A constitution, by-laws and certain rules of conduct were adopted. The Constitution provided for a delegate body, delegates being accredited from recognized medical societies, medical schools and eleemosynary institutions. The rules of conduct prescribed in detail the deportment of a physician, the deportment of the patient, interdicted the licensure of sectarian physicians, and proscribed from consultation those whose practice was based upon an exclusive dogma. The influence of the new Association was extended chiefly through the avenues of the various state societies, many of which adopted the rules of conduct that had been prescribed by the newly formed national body as the basis of affiliation. Several of the state societies, notably those of Massachusetts, Rhode Island and Mississippi, finding either that the prescribed rules of conduct were not suitable to their respective local conditions, or feeling that they were sufficiently in touch with the ordinary forces of civilization to require no such formulæ, never adopted the rules of conduct prescribed by the national body. The medical association of Alabama adopted the rules with rather a naïve proviso that somebody be appointed to call attention to such of the special teachings of these rules "as may seem to require elucidation in view of special circumstances and conditions." Other state societies adopted more or less modifying resolutions, but the general spirit of ostracism and aloofness was maintained during the succeeding three decades. The result of this movement was immediately salutary; it developed an *esprit de corps* in the great body of the profession; it gave an authoritative definition to medical education, and it created a strong and influential national body within the profession. At the same time, however, it became apparent that the organization did not possess the necessary inherent strength to accomplish its avowed object to regulate the practice of medicine. As time passed schismatic medicine grew apace, its colleges multiplied, its practitioners appeared all over the country, exemplifying that law that always makes the blood of the martyrs the seed of the church. Quackery of the most flagrant character was found everywhere, and society was unprotected from its ravages, while the inability of a voluntary unchartered organization to enact and to execute plenary laws was reduced to a demonstration. The medical profession, as an organized body, discovered that its relation to the commonwealth was, as the result of its own

proscriptive policy, scarcely more intimate or more influential than at the beginning of the thirty years' hopeless experiment.

Effective Legislative Control of Medical Practice.—The era of effective legislative control of medical practice came as the natural reaction from the demonstrated failure to accomplish the same result through voluntary organization; but it came as the result of the sentiment which had been propagated largely through the influence of this Association. The representatives of progressive medicine, turning from the National Association invoked the aid of their respective state societies in taking up the question with their respective legislatures. The profession in each state, however, recognizing its own local conditions, proceeded in its own way to attend to its own business. The very earliest attempts to secure state legislation revealed the fact that the so-called irregular practitioners, under the stimulus of ostracism and the fostering care of public sympathy thereby induced, had become so numerous and so influential that in the majority of states nothing could be done without their coöperation. It was no longer a theory, but a condition with which the real reformers were confronted—and they met it. California, in 1876, through its regular medical society, took the initiative. After conferences with the representatives of the sectarian societies, and after securing their coöperation, a law was procured creating a licensing board composed of representatives of both the regular and sectarian schools of practice. Illinois, confronted by precisely the same condition, took precisely the same course. Alabama, always progressive, but the happy possessor of other conditions, was able to place the regulation of medical practice for the time being under the control of its incomparable state medical association. Colorado created a mixed board. New York, confronted by conditions even more complicated than those in other states, took up the same task. The profession of that state, acting through its organized body, containing among its members many of the most honored and illustrious names in American medicine, found it doubly necessary to enter into treaty with the denominational physicians. It realized, however, that the rules of conduct to which it had always conformed contained, among other provisions, one which made it unlawful to "* * * examine or sign diplomas or certificates of proficiency for, or otherwise be especially concerned with the graduation of, persons whom they have good reason to believe intend to support and practise any exclusive and irregular system of medicine."

As the thing expressly interdicted by this rule was the very thing which it was proposed to do, and which had been done in other states, and which was very necessary to do in New York, the medical society of that state amended the rules of conduct so that it or its members might, at discretion, enter into professional relations with any or all persons whom the law of the state at that time recognized to be practitioners of medicine. When this action was brought to the attention of this national body it resulted, not as might have been expected, in the amendment or the abrogation of the rule which had grown obsolete in the march of events, but in its tacit reaffirmation and in the opprobrious excommunication, for the time being, of the entire profession of the great Empire State. This action, viewed impartially after the lapse of nearly twenty years, becomes the more extraordinary when it is observed that similar action was never taken with regard to Massachusetts or Rhode Island or Mississippi, the societies of neither of which had ever adopted the prescribed rules of conduct; nor with regard to California or Illinois or Colorado, each of which had, by overt act, if not by open declaration, so far as this rule is concerned, taken an equally non-conformist position. It is not surprising that, with such an example before the state societies, the experiment in consistency has not been repeated. But the movement of effective regulative legislation, once inaugurated, happily spread with great rapidity. Mixed boards of licensure are now to be found in the majority of the states of the Union, and in the majority of such boards are to be found members of the American Medical Association engaged in issuing licenses to practitioners of exclusive dogmas, and sitting in consultation with sectarian physicians, not over a dose of medicine, but over the vastly more vital question of the qualifications of those who are to care for the sick of our Republic.

The Medical Profession and Society at the Beginning of the Twentieth Century.—The results of the twenty-five years of statutory regulation of medical practice are in striking contrast with the results of the quarter of a century of attempted regulations by methods of proscription. At the conclusion of that humiliating experiment, as at the beginning of it, there was not a single effective medical practice law on the statute books of a single state of the Union. To-day there are forty-eight state or territorial licensing boards, the most of them being composed of representatives of both the regular and the sectarian schools of practice. The laws of the different states are of varying efficiency, the one procured by the Medical Society of the State of New York, at the price of yet-maintained excommunication from this body, standing to-day as the model of excellence for the entire country. Under the influence of these laws, instigated by members of the American Medical Association, and which, after all, are but expressions of the sentiments of the medical profession confirmed by society at large, many substantial reforms have been accomplished. The medical schools which, in this country, have labored bravely and efficiently under adverse conditions, have been stimulated to increased efficiency. One of the first changes accomplished was the practical standardization of requirements to enter practice; and one of the first features of this standardization was to secure for the student

"the aids actually furnished by anatomy, physiology, pathology and organic chemistry"—the four cardinal studies which, strange-sounding as it seems, it was necessary solemnly and specifically to insist upon a half century ago. It follows, therefore, that with broadened and increasingly uniform curricula, it can not be said that schools even of sectarian antecedents entirely "reject the accumulated experience of the profession," nor can it be said that, in a sectarian sense, they any longer possess an excuse for existence. Their graduates, or such of them as do not base practice on an exclusive dogma, are, in many instances, met in formal consultation by even conservative regular physicians, and, in more than one instance, are made members of medical societies that are in affiliation with the American Medical Association.

The Reorganization of the Association.—The demand for more effective organization of the Association has come from all over the country and resulted in the adoption of a motion at Atlantic City authorizing the appointment of a committee of three to report a plan of reorganization at this session. Another motion was adopted authorizing the creation of a supplementary committee of one from each state and territory, entitled a Committee on Organization, which has been filled by appointing for the most part the retiring presidents of state societies for the current year. The Committee on Reorganization, consisting of Dr. J. N. McCormack, of Kentucky, Dr. George H. Simmons, of Illinois, and Dr. P. Maxwell Foshay, of Ohio, has given to the important question entrusted to it a most careful and painstaking deliberation. It has laid before you the results of its deliberation. In doing so it has emphasized the principle that this Association has its origin in the organized profession of the respective states. It emphasizes the fact that the delegate body should be so small that it can remain in prolonged session and give to various subjects under consideration that deliberate attention which has not been possible under the existing scheme of organization during the last forty years. It recognizes the paramount importance of the scientific feature of our work by relieving the general meetings and the sections alike of the troublesome details that now consume the limited and valuable time of the Sessions. It remedies the glaring and serious defects in the present constitution. It prepares the Association, by perfecting the organization, to meet important and pressing questions. These considerations, together with the fact that the existing constitutional provision relative to delay of action on pending amendments has been met by the appointment, a year ago, of a committee for the avowed and published purpose of reorganization, and by the action of the committee in laying the results of its work before every member of the Association—I say these considerations, and these facts, prompt me to advise the adoption of the proposed Constitution and By-Laws in their entirety at the present annual session of the Association.

The Committee on Reorganization, under the restrictions of the resolution creating it, has, very properly, left undisturbed the existing rules of conduct. These, if construed to have a fundamental importance, and if vigorously enforced as they now stand, would disintegrate the Association in a single day. This reason, and others already given, confirm me in the conviction that such rules should be either amended or abrogated, or, if reaffirmed, it should be by general resolution endorsing their underlying principles but disclaiming the present applicability of their details. There are, however, various views entertained upon the subject, and that the matter may be approached in a spirit of tolerance may be discussed coolly and impartially, that a consensus may be reached, and that harmony may be attained, I recommend that the general questions of the revision of the rules of conduct be referred to a special committee on ethics, consisting of three members, with instructions to report to the legislative body at the next annual session of the Association.

The New School of Medicine.—The changes which I have advocated are essential for the attainment of the purposes of the Association and for the fulfillment of the high destiny of our National profession. They are demanded by the changes that have taken place during the last fifty years. The legislative functions have passed from voluntary organizations to the Congress and the legislatures, where they belong; but it still devolves upon the profession in the organized capacity, to stimulate, to restrain, or otherwise to control the law-making power. The responsibility of the profession is increased, rather than diminished. Science has come to have a clearer meaning. He who now proclaims a dogma cries alone in the night, while the world sleeps. They who demand a creed may read its varying terms only in the progressive revelation of natural laws. Practice has changed. The depletions, the gross medications, the absurd attenuations, the ridiculous antimineralism have given way to a refined pharmacy and to a more rational therapy. Sacrificial surgery has yielded to the spirit of conservatism. Prevention is given precedence over cure. Education implies research and discovery, and all may delve. I proclaim, events proclaim, the existence of a new school of medicine. It is as distinct from the schools of fifty years ago as is the Christian dispensation from its Pagan antecedents. It is the product of convergent influences, of diverse antecedent origin. It acknowledges no distinctive title, it heralds no shibboleth. It is a school of human tolerance, of personal independence, of scientific honesty. It is the slave of neither prejudice nor preconception, and abandons the accepted truth of yesterday, if it only be the demonstrated error of to-day. It places no premium upon personal prerogative, and extends no recognition to in-

dividual authority. It makes no proclamation of completeness, no pretention to sufficiency. It recognizes that truth is undergoing progressive revelation, not ending to-day, but continuing through the ages. It yields its plaudits to achievement, and recognizes that he is the greatest among men who reveals the most of truth unto men. It greets as a friend him who thinks, though he think error, for, thinking, he may think truth and thereby add to the common fund. It heeds all things, examines all things, judges all things.

To you, the exponents of this new school, of this new generation, of this new century; to you, representatives of the Democracy of Science; to you citizens of the Republic of Letters, I extend greetings; and here, in our parliament assembled, here, where our will is supreme, I this day invoke upon our deliberations the spirit of liberty, the spirit of courage, the spirit of progress, the spirit of truth.

INTERNAL MEDICINE IN THE NINETEENTH CENTURY.[1]

BY N. S. DAVIS, JR., M.D.,

OF CHICAGO.

IT is one of the duties of those who address you, as I do to-day, to review what has been newly discovered in the field of medicine or in some limited department of it. At this first meeting of the American Medical Association in the twentieth century, it seems most natural to review what has been accomplished in the last one hundred years. The time at my disposal is too brief to read to you a complete history of the achievements of this wonderful epoch, for more of genuine advancement has been made in medicine during it than during all the preceding centuries together. It is only possible for me to point out some of the reasons for the rapid development of medicine, to recall to your minds some of the most important discoveries and applications of them.

The wonderful, the revolutionary discoveries made by students of internal medicine during the nineteenth century are not always appreciated as they should be, for their results are often demonstrable only by statistics: and the dramatic rescue of individuals from certain death which the surgeon at times accomplishes, unfortunately cannot be effected by the therapeutist. It is not in the nature of his art. Great progress, however, has been made in the use of medicines and remedial procedures. Good reasons can be given for their employment, and their mode of action can be explained. Empiricism no longer governs their use as it formerly did. The placing of therapeutics upon a scientific basis began in the last century when the physiological effect of drugs was first demonstrated by experiments upon animals.

No field of medical research needs cultivation so much or is more certain to yield a rich harvest than therapeutics. It is surprising that we have not a larger volume of accurate knowledge of the effect of drugs than we do possess. Of late pharmacology has been neglected for studies which have temporarily been more enticing to experimenters, such as bacteriology and experimental pathology. Moreover, a knowledge of these subjects is essential to enable a clinician to apply his therapeutic resources to the mitigation of suffering, the support of strength, and the elimination or destruction of noxious substances. One can safely prophesy that the exact utility and the limitations of drugs and medical procedures will be defined in the present century.

To accomplish this, not only is more knowledge required of the physiologic action of drugs, but also better means of accurately measuring their effects when they are given to patients. We know when pain is relieved we can sometimes measure effects produced upon the heart and blood-vessels and temperature. Beyond this we depend for knowledge upon the impressions of physicians, impressions which must be corrected and often reversed by a wide experience. Clinicians possess only a few appliances or methods for the exact study of the sick. It is to be hoped that more will be discovered, and that they will also make it possible to register with accuracy the effect of drugs. When this is accomplished, undoubtedly a smaller number of useful drugs will be employed, but these with greater exactness.

It is true that more drugs are used to-day than need be, because patients demand them as a fetish; but this will be changed when laymen learn that it is the function of the physician to teach them what to do to give Nature the best chance to effect repair, what to do to make themselves comfortable and to preserve life. Then they will learn that it is a physician's function to teach them how to protect others from the same ailment, to foretell the possibility of recovery or death, and to avert or forestall complications. Medical men should include time and faith in their materia medica as an important means of effecting a restoration of health. I do not mean faith in a fetish procured in an apothecary's shop, but faith in the wisdom, honesty and disinterested devotion of physicians which will enable them to accomplish all that can be done for the suffering.

Although the greatest discoveries in the field of internal medicine have been applicable to the prevention of illness in the masses, much has also been done to increase the chances of recovery of individuals who are sick. I need call attention only to a few of the improvements in treatment which have been effected

[1] Annual Oration in Medicine, delivered at the Fifty-second Annual Meeting of the American Medical Association, held at St. Paul, Minn., June 4-7 1901.

to remind you of more. Typhoid fever, which has been a scourge in all civilized countries, and constantly present in all large centers of population, has not only been greatly lessened, sometimes even suppressed by improved hygiene, but the chances of recovery of the one who is sick with it have been increased several fold by improved methods of treatment. Twenty-five years ago the mortality from typhoid fever in the hospitals of the world was from 20 to 35 per cent.; to-day it is from 5 to 15. The better results are due to the cold baths which are used, to a more generous supply of fresh air, to proper feeding, and to protection against, or the prompt treatment of, complications.

One great therapeutic discovery has been made at the end of the nineteenth century—the discovery of antitoxins, the natural antidotes to the poisons of infectious agents. For a very long time it had been known that something developed in the human system during the course of many ailments which gave to the sufferer from them for a variable time immunity from a recurrence of the same disease. Until the existence of parasites and of poisons generated by them was proven, an antitoxin was of course unrecognizable. Moreover, the possibility of such a thing in diseases, one attack of which did not cause immunity to others, was not even suspected. But the diphtheria antitoxin, the most efficient of those of which we know anything, is one belonging to this last group of ailments. The chemical composition of antitoxins is yet to be discovered. Since antitoxin has been used the mortality from diphtheria has been reduced about one-half. The most extensive collection of statistics gathered from all civilized countries shows that when antitoxin is used on the first day of the disease, the mortality is 5 per cent., increasing rapidly to 30 per cent. when used on the fourth day or later. Before its employment, the average mortality of the disease was from 25 to 35 per cent. To effect a still greater reduction in the death-rate from this ailment, it is necessary that it be recognized early, and that antitoxin be employed more generally as a preventive for those who have been exposed.

That tetanus antitoxin and plague antitoxin are valuable is admitted. Many others, such as pneumonia, typhoid, tubercle, scarlet fever, erysipelas and streptococcus antitoxins are still in the experimental stage. But even though it should be found that few natural antitoxins can be isolated for use as remedies, those already discovered confirm physicians in the hope that specifics will be found some day.

Another therapeutic discovery made at the close of the century which has thrown a flood of light upon some obscure points in physiology and pathology, and has restored to usefulness many who were formerly incapacitated and incurable, is that of internal secretions, and especially the rôle of the secretion of the thyroid gland. Ingredients in the thyroid, suprarenal bodies, and ovaries, produce as definite effects upon the living body as many extracts from plants or synthetic chemicals. The pituitary body, the thymus, and bone-marrow may also have a value as yet undetermined. The rescue of those suffering from myxedema and cretinism by the administration of thyroid is one of the few happy dramatic incidents which fall to the lot of the practitioner of medicine.

That a much larger proportion of recoveries from tuberculosis occurs to-day than formerly is evident from the statistics of this disease, but this lessened mortality is not due to prevention only. Trudeau has estimated that 18 per cent. of all persons have tuberculous lesions, because a reaction to tuberculin can be demonstrated in that proportion. This statement is confirmed by Councilman, who states that his autopsy statistics show that at least 17 per cent. of all who die have had this disease. But in spite of this prevalence the mortality from the ailment is lessening.

Rabies and tetanus are two diseases which until recently were thought to be incurable. Rabies can be suppressed by killing unowned dogs and by muzzling the rest. Upon this point the following statistics from England are very instructive. In 1887, 217 deaths occurred in Great Britain from rabies; in 1888, 160; in 1889, 312. A muzzling law was then enforced. In 1891 the death-rate from the disease fell to 129; in 1892, to 38. The muzzling ordinance was repealed, with the result that in 1894, 248 deaths occurred from mad dog bites, and 672 in 1895. Again muzzling was made compulsory. The death-rate once more diminished; in 1897 it was 151; in 1898, 17; in 1899, 9, and in 1900, none!

Tetanus, quite common in hospitals formerly, is now prevented by properly cleansing and protecting wounds. It has become so rare a disease that to-day most students do not see a case of it during their college course.

The nineteenth century will be known in the history of medicine as the century of experimental medicine, for it is in that field that the greatest discoveries of the age have been made. The names of Pasteur, Koch and Lister will forever be linked with it as representing its greatest achievements. But these achievements would not have been possible had not the physicist perfected the microscope, and had not Virchow and his pupils explored the field of cellular pathology to its farthest limits. Around Virchow's name as a banner will historians gather the achievements in medicine during the early and middle portions of the century, and around Pasteur's those of its close.

If our greatest needs conditioned the growth of knowledge, we could prophesy what will be the great field of research of the twentieth

century, but history teaches us that our needs can often not be met until some sister science has grown, or new methods of experimenting have been devised. Therefore, the future must remain a blank to us. However, we are more apt to accomplish what is needed if the problems are kept clearly in mind. We greatly need more exact methods of clinical study, more accurate knowledge of the effect of remedial agents and procedures, but more than all else we need a knowledge of the changes which take place in the living tissue in health as well as in disease.

The anatomist has resolved the cellular structure of the body; the physiologist, the laws which govern the action of its organs and the chemic changes which are wrought upon its surfaces; the bacteriologist has discovered the parasites that infest, and often destroy it; the pathologist has described the anatomical changes which disease produces; the clinician has linked all these facts together and has discovered ways of seeing with the intellectual eye disturbances of physiologic function, of determining their cause, and of anticipating the anatomic changes which they will produce. But this does not satisfy us; we want a knowledge of the atomic and molecular structure of cells, of the changes which take place in the atoms and molecules in health and in disease, and of the effect of medicines and remedial procedures upon them. This knowledge chemistry must give us. I feel sure that, standing as we do at the beginning of a new century, expecting greater developments in it than in the last one, we are halting before new discoveries in chemistry, waiting for new methods of studying metabolism in microscopic portions of tissue. When this knowledge is vouchsafed, medicine will make another stride as great as was made when, by the perfected microscope, cellular pathology and bacteriology became possible.

Let us look forward with confidence to the Virchow and the Pasteur of the future.

THE VALUE OF CLINICAL MICROSCOPY, BACTERIOLOGY AND CHEMISTRY IN SURGICAL PRACTICE.[1]

BY JOHN A. WYETH, M.D.,
OF NEW YORK

FOR many years, almost without exception, my predecessors in the address on surgery have devoted their labors to the exposition of some general or special subject in the domain of operative surgery, and while I would in no measure detract from the value of a thorough technical knowledge, we should not in our attention to the *art*, fall short of a proper appreciation of the *science* of surgery.

The experienced surgeon soon learns that it requires more than asepsis and the rapid and skilful performance of an operation to achieve the fullest measure of success; that although a thorough practical knowledge of regional anatomy is essential in the highest degree to the conscientious fulfilment of the professional obligation, it is equally important that there be called into requisition the invaluable aid which laboratory research alone can give in determining an accurate diagnosis; in indicating the most rational measures of treatment not only in the preparation of a patient for an operation, and in the selection of the safest anesthetic, but for the post-operative management of the case, and in removing as far as posible all doubts as to the prognosis.

Chemical analysis of the normal and abnormal secretions and excretions of the body, *clinical microscopy* and *bacteriology* should form a part of the educational requirement of every surgeon. I do not insist that the busy practitioner should attempt to master all the intricate processes of the laboratory, for this is only possible to one who devotes years of patient labor in the fascinating department of science, but he should possess that practical knowledge of chemistry of the body in health and disease, and of clinical microscopy and bacteriology which any diligent student, under a competent teacher, and in a properly equipped laboratory, should be able to acquire in a three months' course of study.

The instances are exceptional in practice where this knowledge cannot be applied with great benefit to the patient, and with satisfaction to the surgeon. It is naturally of greatest value in the cases where no emergency for immediate operation exists, but its advantages are not wanting in these rarer cases, since it comes to his aid in the post-operative period.

To the surgeon, one of the most gratifying results of the great triumph of the laboratory in the treatment of diphtheria is the fact that he is now rarely called upon to perform the operation of tracheotomy which was formerly distressingly frequent; nor to witness the sufferings associated with intubation of the larynx. A professional friend in the department of diseases of children informed me recently that whereas a few years ago he had from 10 to 20 intubations of the larynx on account of diphtheria in every month, he now, since the serumtherapy was practised, averaged only one or two.

I believe that what is true of this disease is true of all infectious processes, and that as our knowledge expands, a safe immunizing serum will be discovered for each special toxemia. Even now it would seem that this proposition is proved in other infections in which like diphtheria the pathogenic organisms are localized at the seat of infection, their toxic products alone entering the tissues through the circulation.

Tetanus toxemia, or "lock-jaw," the organism producing which was discovered by Nicolaier in 1894, and which for years has baffled the most strenuous efforts of the bacteriologist and clinician, seems at last to be classified with the con-

[1] Abstract of the Oration on Surgery before the Fifty-Second Annual Meeting of the American Medical Association at St. Paul, Minn., June 4-7, 1901.

trolable infections. Professor Osler, in the last edition of his "Practice of Medicine," says the immunizing serum of Tizzoni has been successfully and encouragingly employed in doses of 2.25 grams for the first dose, and 0.6 gram for subsequent doses. Of 113 cases treated by this method 63 per cent. recovered.

The practitioner who has not called into requisition the invaluable aid which bacteriology affords in the differentiation of those too often obscure intraperitoneal lesions, cannot appreciate the satisfaction which this practical application affords. How often the safety of a patient hangs upon even a few hours' time, and alas, how often this precious time is wasted in the uncertainties of diagnosis, when a resort to the demonstration of science, available to all, would have plainly indicated the proper method of procedure. We know too well the fallacy of relying upon the ordinary subjective symptoms, and even some of the objective symptoms afford us no accurate clue to the pathological process which may exist. The pulse and the temperature of commencing typhoid may well be mistaken for the pulse and temperature of an appendicitis. The pain and muscular resistance over the right iliac and the right abdominal region are in many instances practically alike. The nausea, the vomiting, and the general sense of uneasiness point neither directly to the one nor to the other disease, but in a crucial test by Widal's reaction, with the blood-count pointing to the presence or absence of a leucocytosis, the question is quickly settled. I have seen all the symptoms of appendicitis present in cases in which the blood-count contradicted a pyogenic sepsis, and in which Widal's reaction told the story of typhoid. On the contrary, I have dealt with cases which ordinarily would have been most perplexing, in which all the symptoms of typhoid prevailed at a period when it was too early to recognize this disease by Widal's test, and a leucocytosis of from 15,000 to 21,000 proved at the earliest possible moment that the case was one for immediate operation.

In another fortunately rare disease, malignant pustule, caused by the lodgment in an abrasion of the bacillus anthracis, we are indebted to the laboratory for our knowledge of its etiology. The anthrax bacillus discovered by Devaine in 1863 is not usually found in the blood except in the most malignant cases, and in the last stages of fatal infection, but they can be demonstrated in the pustule of inoculation with the microscope or by cultures.

Not only does the laboratory come to our assistance in the diagnosis of certain obscure surgical lesions of the stomach, but it is still more valuable as an aid in arriving at the exact condition of the digestive functions of this organ, any derangement of which it is at times exceedingly important to correct in order to bring a patient into suitable condition to stand an operation. Thus it is important to determine in certain instances whether or not free hydrochloric acid exists in this organ, and while the total quantity poured into the stomach in the digestive process cannot be accurately measured, clinical chemistry can closely estimate the total quantity found at a given moment during digestion. The acid-combining power of the proteids is known, and by certain tests it is feasible to estimate sufficently close for a satisfactory diagnosis, the quantity of hydrochloric acid secreted. The small quantity of hydrochloric acid which combines with ingested inorganic elements is lost to gastric digestion, serving as it does its function in this process in the intestines.

A study of the discharges from the rectum is as yet of little value to the surgeon. Beyond the recognition of blood or pus, or cast-off cell elements in certain malignant neoplasms, there is but a single organism which is of real diagnostic value, namely, the amœba of dysentery, described by Lamb in 1859, which is a motile mass of prōtoplasm about 20 micromillimeters in diameter containing a single nucleus, and one or several vacuoles.

In the differentiation between the pathogenic organisms of specific and non-specific urethritis, microscopy and bacteriology are our only infallible guides. They teach us to eliminate the various bacteria found in the external genital and urinary passages, not bearing directly upon the etiology of urethritis, and to recognize distinctly the two forms of diplococcus, the gonococcus of Neisser, and the pseudo-diplococcus, which, while not morphologically different from the specific disease-producing organism, can be readily distinguished by special modes of staining as well as by cultures. In the daily routine of practice the exact nature of every suspicious urethral discharge should be subjected to careful scrutiny.

The presence of the bacilli of tuberculosis in one or both kidneys, even when they are exceedingly infrequent in the discharge, can be demonstrated in urine drawn by urethral catheterization, or by the more simple process of bladder segregation, when the suspected organisms are with other detritus thrown down by the centrifuge.

In the effort to arrive at the general condition of a patient, the chemical, microscopical and bacteriological study of the urine is only second in importance to that of the blood, and when we consider the additional and exact information which can thus be obtained concerning any pathological process at any point in the urinary tract, the value of this analysis is very materially increased. A careful study of the urine is always indicated before determining what anesthetic it is safest to employ in the operation to be undertaken. When there is no important lesion of the heart, either in its valvular mechanism or in the blood supply and nutrition of its muscular walls, few surgeons, I hold, would employ ether in a protracted operation in which there was any suggestion of an acute nephritis, or in certain chronic forms of Bright's disease.

The presence of oxaluria is in my opinion a

contra-indication to a serious surgical operation, for the reason that it is pathognomonic of a disturbed nutrition due to insufficiency of the digestive fluids, and to fermentative processes in the intestinal tract.

The chemistry and microscopy of the urine further informs us when ammoniacal decomposition of the urine is taking place within the bladder, suggesting insufficiency of this organ due to obstruction of the urethra or to atony of the bladder muscle. The large rhombic masses or stellate and cross-shaped rosettes of the triple phosphates only exist in these abnormal conditions of the bladder, and with the brownish-colored, thorn-like crystals of urate of ammonia are important aids to diagnosis.

The presence of epithelia from the various portions of the urinary or genito-urinary tract, of spermatozoa and various bacteria chiefly pyogenic in character, are further and well-recognized evidence of the value of the microscope in surgical diagnosis. In rarer instances, the hooklets of echinococcus, the embryos of filaria and the ova of hemotobium Bilharzii are thus discovered in the urine.

When blood is found in the urine as a complication of papilloma of the bladder, particles of the broken-down tumor are very frequently found in the urine, and under the microscope the epithelial elements of this neoplasm are easily recognized and point clearly to the source of the hemorrhage. In hemorrhage from the kidney substance blood casts tell unmistakably of its source.

To-day, one of the most attractive subjects of laboratory research is the blood. Although hematology is practically in its infancy, many valuable discoveries have already been made, and in the proper study of a patient, a knowledge of the blood is as essential as that of the urine. It may throw no light upon many cases, but the reward will be tenfold in that particular instance where the diagnosis is made definite and clear. It is necessary to know the normal blood thoroughly by constant practice in order to recognize the abnormal changes which may be present in a given case, and I can think of no more useful way of spending the time not taken up by practice than by going over these important features of laboratory technic.

A knowledge of hematology enables the surgeon to detect any form of anemia and to determine whether it is a type of blood impoverishment which can be corrected, or whether it is of the graver or more pernicious forms which would either preclude an operation, or, if this were absolutely necessary, would enable him to announce to those entitled to information, the gravity of the outlook. In ordinary practice it is not always essential to differentiate between a pernicious anemia or a leucemia, or whether this latter condition is present in the lymphatic or splenic-myelogenous form, for the reason that all of these graver varieties call a halt to operative measures when these can be avoided. But the anemia which comes from malnutrition or malaria, or chlorosis, can be positively diagnosticated by a study of the blood.

The richness of the hemoglobin may in a fair measure be determined by the comparative color test of the blood in proper solution, as observed through Von Fleischl's hemometer. When a low percentage of hemoglobin is present, it is an indication to avoid any operative shock until the impoverished condition of the blood can be corrected by proper nourishment, by rest, or by medication, when this is positively indicated. This also suggests the aid of the microscope in a further investigation as to the condition of the corpuscular elements of the blood.

The surgeon would be extremely unfortunate to fail in the recognition of these often obscure lesions, and if possible to correct them before subjecting his patient to the severe ordeal of an operation. In the early recognition of septic processes—chiefly pyogenic—surgery can no longer disregard the value of the blood-count, especially the estimation of the leucocytes.

The relative number of leucocytes in a given quantity of blood, or their proportion to the red corpuscles, can be readily determined by the use of the Thoma-Zeiss apparatus which, as is well known, consists of two pipettes, one for the red and one for the white, with a well outlined and peculiarly constructed slide or counting apparatus, and employed with the ordinary one-sixth laboratory objective. The differentiation by the use of the Daland hematocrit, is not considered sufficiently exact to be satisfactory in the hands of the majority of hematologists. It is essential in making these differentiations to bear in mind the normal conditions that at the sea level the average number of red cells per cubic millimeter is 5,000,000 in men, and 4,500,000 in women, and 6,000,000 in the young and more vigorous adults, while the white cells average about 7,500 per cubic millimeter for each sex.

Certain conditions not considered normal, influence the number of leucocytes since in the latter months of pregnancy they are moderately increased, and after parturition, and during the early weeks of lactation, a leucocytosis may be present, without pathological significance. After hemorrhage the leucocyte count is increased, and in diphtheria, erysipelas, trichinosis, all extensive forms of endometritis and all acute pyogenic processes, leucocytosis exists except in those cases where the vitality of the individual has been overwhelmed by the severity of the septic process, under which condition the leucocytes no longer respond to the demand for the protection of the tissues, and are not present in the superficial blood in even normal proportions. It is probable that the application of this knowledge is more profitable at present in the study of the various lesions of the abdominal and thoracic organs. We know that in a certain proportion of cases of infection, temperature does not always indicate the increasing gravity of the lesion, while the degree of sep-

sis can be in great measure determined by the leucocyte count. In impaction of feces, extra-uterine pregnancy, floating kidney, gall-stone, renal colic, ovarian neuralgia, intussusception, volvulus, inguinal hernia, twisted pedicle, etc., there is no leucocytosis unless complicated with an acute septic process. In abscess of the liver the leucocyte count ranges from 12,000 to 48,000, while there is a well-marked increase in all the septic pyogenic processes of the lungs and the pleura.

In osteomyelitis the leucocyte count ranges as a rule from 15,000 to 25,000, and at times higher. Since in the early stages of this disease it is at times difficult by subjective symptoms to differentiate between rheumatism or gout, the leucocyte count is invaluable in demonstrating at once the pyogenic process.

In that very rare disease, trichinosis, the leucocytes register sometimes as high as 30,000, but the special feature is the presence of a large number of eosinophile cells, sometimes as high as 50 per cent., and in rare cases 67 per cent. of the total number of leucocytes being this form of corpuscle. A very considerable number of cases have been reported within the last year in which the diagnosis has been determined by the presence of eosinophiles.

THE PROGRESS AND TENDENCY OF HYGIENE AND SANITARY SCIENCE IN THE NINETEENTH CENTURY.[1]

BY GEORGE M. KOBER, M.D.,
OF WASHINGTON, D.C.;
PROFESSOR OF HYGIENE, GEORGETOWN UNIVERSITY.

Hygiene is a department of medicine whose object is the preservation and promotion of health and deals, therefore, with all the factors likely to influence our physical welfare. It is not an independent science, but rather the application of the teachings of physiology, chemistry, physics, meteorology, pathology, sociology, epidemiology and bacteriology to the maintenance of the health and life of individuals and communities. The subject is very properly divided into personal and public hygiene. In the former the doctrines are applied to individuals, in the latter to communities and States.

This branch of medicine has received such an impetus within the last few decades that many persons regard it of modern origin; such, however, is not the case, for on turning to early history we almost invariably find that the health of the population has been made a subject of legislation. Hygiene was practised by the Egyptians, the old Indians and Hebrews, and a study of the habits of the primitive peoples shows that a desire to prevent disease is innate to all men.

The Greeks and Romans paid special attention to the physical culture of their youth; they also paid much attention to the water supply, and Athens was provided with sewers at an early period of her history.

The teaching of Hippocrates, 400 B. C., doubtless bore many fruits, and whether it is true or not, as stated by Galen, that he ordered, during a pestilence at Athens, aromatic fumigation and large fires in the streets, we have at least his writings on air, water, soil, habitations and occupations and his views of local and seasonal influences on sporadic and epidemic diseases. In Homer's "Odyssey" reference is made to Ulysses purifying his house with burning sulphur, and Aristotle, in his "Politica," shows his sanitary acumen when he says: "The greatest influence upon health is exerted by those things which we most freely and frequently require for our existence, and this is especially true of water and air."

The Romans, amidst their military operations, found time to construct the "Cloaca maxima" about 2,400 years ago, which not only served for the removal of refuse, but also helped to drain many of the marshes, and constitutes the principal sewer of modern Rome.

Pests and Insanitary Conditions of the Middle Ages.—About this time most of the towns in Europe were built in a compact form, surrounded by walls; the streets were narrow and often winding for defensive purposes, shutting out light and air from the houses. The accumulation of filth was simply frightful. Stables and houses were close neighbors, human filth was thrown on the streets or manure heap. The dead were buried within the churchyards. Sewers and aqueducts having been permitted to fall into disuse, the inhabitants were compelled to resort to wells with polluted subsoil water. All the conditions were favorable for the spread of infectious diseases and in the fourteenth century alone the Oriental or bubonic plague, according to Hecker, carried off one-quarter of the population of Europe, or over twenty-five million victims.

The repeated invasion of the Oriental pest appears to have everywhere compelled some sanitary efforts and an imperial decree in 1426 required the appointment of city physicians throughout Germany, whose duty it was to adopt preventive measures. A city ordinance of Nürnberg in 1562 gives detailed directions as to the quality of bread, beer and wine offered for sale, the cleaning of streets and houses, the disposition of infected clothing and bedding, the fumigation with sulphur and straw of pest-houses, etc.

With such insanitary conditions we need scarcely be surprised that the mortality in towns was greater than their birth-rate and that the city population had to be recruited continually from the country. Toward the close of the eighteenth century many sanitary reforms were effected, however, especially in connection with infant and orphan asylums, and the management of schools and prisons. Of special importance is the brilliant discovery, or re-discovery, of vaccination by Jenner in 1796.

Progress of Sanitation in the Nineteenth Cen-

[1] Abstract of the Oration on State Medicine before the Fifty Second Annual Meeting of the American Medical Association at St. Paul, Minn., June 4-7, 1901

tury.—The nineteenth century can boast of many advances in hygiene, particularly since the European invasion of cholera in 1830. The English towns which had been visited by this disease and those fearing similar scourges were willing to profit by their sad experience and freely instituted sanitary reforms in the establishment of sewers, public water supplies, sanitary homes, etc.

The example of England was followed by all civilized nations with similar results. The efforts of sanitation, as taught by Dr. Parkes, were demonstrated during the Crimean War and, as beautifully expressed by Virchow during our Civil War, reached "the highest point in humane efforts ever attained in a great war," and we may proudly add have even been excelled during our late Spanish-American war.

Progress of Sanitation in the United States.—While the people of the United States were not slow in adopting and originating sanitary measures of great value, our ideas of personal liberty, guaranteed to us by the Constitution, evidently prevented early legislation in matters of public health, for fear that such legislation might affect the personal habits of the citizen and lessen his freedom of action. Dr. Samuel W. Abbott, in his masterly exposition of "The Past and Present Condition of Public Hygiene and State Medicine in the United States," records, however, the gratifying fact that the early colonists recognized the need of preserving their records, which constitute the foundation stone of public hygiene, by enacting a law in 1639 "that there be records kept of the days of every marriage, birth and death of every person in this jurisdiction."

The importance of vital statistics is not fully appreciated at the present day, and yet, as remarked by Dr. Billings, "when we wish to study the healthfulness of a city, whether it is getting better or worse, or judge correctly the effect of certain sanitary laws, we should not only know the number of deaths, but also the amount and character of the prevalent disease, together with accurate information as to the number of population at different ages." It is a matter of regret, therefore, that even now only ten States, Connecticut, Delaware, Maine, Massachusetts, Michigan, New Hampshire, New Jersey, New York, Rhode Island and Vermont, have anything like a satisfactory system of vital statistics.

According to Abbott, "Up to the close of the eighteenth century and for several decades of the nineteenth, almost the only health legislation which was enacted in the different States in the Union consisted in a few laws relating to smallpox, since this pestilence was scarcely ever absent for many years at a time from any city or village, 'till after the general introduction of vaccination."

Dr. Waterhouse, of Cambridge, having secured a supply of vaccine lymph from Dr. Jenner, introduced vaccination in Boston in 1800, and Dr. Seaman in New York in 1801. In the same year President Jefferson received some virus from Dr. Waterhouse and was vaccinated by Dr. Grant, of Georgetown.

Health Boards.—New Orleans having lost 8,000 victims of cholera in 1832, out of a population of about 55,000, and anxious to maintain a quarantine, secured the enactment of a law in 1855 for the establishment of a State board of health; in 1869 a more comprehensive board was established in Massachusetts, followed in 1870 by California, since which time nearly all of the States and Territories —forty-two in number—have followed the example. *Pari passu*, and in many instances preceding the establishment of State boards of health, sprung into existence our local boards of health, who adopted measures for the control and restriction of infectious diseases, for the abatement of local nuisances, for the sanitary inspection of the food-supply, schools, public buildings and institutions and tenements; street cleaning and removal of refuse, registration of vital statistics, supervision of burials and of municipal water-supply, sewerage, and sewage disposal, care of bathing establishments, regulation of offensive trades, etc.

In September, 1872, the American Public Health Association was organized; in 1873, the Section on State Medicine of the American Medical Association was created; since then the American Climatological Association, the Sanitary Council of the Mississippi Valley, the American Sanitary Association, and the American Health Resort Association have been organized, and numbering, as they do, among their members some of the best minds in the profession, much good has been accomplished by these bodies, and the so-called "sanitary conventions" in molding public opinion and in framing and recommending health laws.

Indeed, the American Medical Association, according to Dr. N. S. Davis, Sr., gave prominent attention to State medicine and sanitation from its first meetings. At the second annual meeting, in 1849, standing committees were appointed on forensic medicine and on hygiene and reported annually on these topics and on meteorology, medical topography and epidemic diseases until 1860, when work in sections was commenced. Dr. A. N. Bell, of New York, delivered the first address on State medicine in general session of the Association in 1874, followed in 1875 by Dr. N. I. Bowditch, of Boston. In this connection, I may say that there is need of reliable information on the geographical distribution of diseases like goiter, cretinism, etc., and county medical societies would contribute much to the common fund of knowledge by placing on record information of this character.

National Board of Health.—The cholera epidemic of 1872 and 1873 resulted in the appointment of a commission by Congress. This, together with the yellow-fever epidemic of 1878 in the Southern States, affecting, according to Sternberg, over 74,000 persons, with 16,000

deaths, called attention to the necessity of some central sanitary organization. In March, 1878, Congress created a national board of health, whose duty it was to make investigations into the causes and means of prevention of contagious and infectious diseases, to indicate measures of national importance and to be a center of information for all matters relating to public health. For want of appropriation this important body has ceased to exist, and since 1883 the duties relating to international and interstate quarantine have been discharged by the Surgeon General of the U. S. Marine Hospital Service.

National and International Quarantine.—The question of an efficient system of national and international quarantine against Asiatic cholera, yellow fever, smallpox, typhoid fever, bubonic plague, and leprosy has engaged the attention of sanitarians for years, especially since it became known that these diseases, particularly cholera, are generally carried along the highways of travel and commerce. General Wyman's plan, as outlined in his address before the Pan-American Medical Congress, contemplates an international system of sanitation; while his proposition refers especially to yellow fever in the Western Hemisphere, it is equally applicable to the home of cholera and the Oriental plague.

Has Human Suffering Been Mitigated, and Human Life Been Greatly Prolonged by Efforts in Sanitation?—Our answer is an emphatic "Yes." Professor Finkelnburg, of Bonn, estimates that the average length of human life in the sixteenth century was only between 18 and 20 years; at the close of the eighteenth, it was a little over 30 years, while to-day it is over 40 years; indeed, the span of life since 1880 has been lengthened about six years, as shown by statistics, in Mulhall's "Dictionary of Statistics" (4th edition, London, 1899).

The mortality of London between 1660 and 1678 was 80 per 1,000 of inhabitants; from 1728 to 1780, 51 per 1,000; from 1801 to 1835 it was still 29, while at the present time it averages between 17 and 19 per 1,000.

Without underestimating the brilliant achievements of Jenner's discovery of vaccination in 1796, which as a preventive measure has saved millions of lives, no two factors have contributed so much to the general result as the improvement of the air we breathe and the water we drink.

The history of every sewered city shows a lessening of the typhoid death-rate subsequent to the construction of the sewers and that the typhoid rate is always higher in sections supplied with privy pits and box privies, than in the houses connected with sewers.

Influence of Improved Water-Supplies.—A summary of the evidence on this subject reveals the significant fact that cities, both at home and abroad, in which there has been the most marked decrease in typhoid-fever death rate, are those in which a pure supply has been substituted for a pre-existing contaminated one.

When we remember that in 1896, 41 per cent. of our population lived in towns having public water-supplies, and only 28.7 per cent. in sewered towns, we fear that the municipal authorities have failed to recognize the necessity that a system of public sewerage must go hand in hand with the public water-supply, the neglect of which simply compels recourse to the various makeshifts for the collection and removal of excreta, and leads to soil pollution and all the other evils already referred to.

In view of the fact that self-purification of rivers is a slow and uncertain process, and that streams once polluted with excrementitious matter can not be considered a safe water-supply, it is high time for civilized communities to take steps toward removing the danger to be found in rivers, which are the sewers and at the same time the sources of public water-supplies.

One of the most pressing needs is an investigation into the pollution of water-supplies when such pollution affects or threatens to affect the sanitary condition of the people of more than one state, because the individual states are powerless to protect themselves against the misdeeds of their neighbors.

No community or individual has a right to pollute streams used for public water-supplies any more than a man has to contaminate his neighbor's well. This principle is very well appreciated by some of the nations in Europe. Thus the inhabitants of a town in Belgium suffered from the effects of a river polluted by the French and the French Government not only compelled the offending town to dispose of its sewage by irrigation, but also granted a subsidy for this purpose.

Pure Food and Drug Legislation.—The first movement toward securing comprehensive legislation against the adulteration of foods and drugs in this country was made in 1879. This is all the more surprising because Dr. Mann, in his "Medical Sketches of 1812," remarks that "the bread on the Niagara was made of damaged flour, such as was either not nutritious or absolutely deleterious." It was believed also that the flour contained in some instances an earthy substance, and that this adulterating substance was plaster of paris. Again, during the Civil War, as early as the winter of 1861-62, an extract of coffee furnished the troops in the vicinity of Alexandria produced nausea and vomiting, and subsequently a government contractor, for having practised food adulteration, was sentenced to a protracted imprisonment.

Some adulterations are harmful, others are not. I will simply refer to a very universal article of food, viz., milk. New York City obtains its milk-supply from five States, and amounted in 1896 to nearly 720,000 quarts a day. Analysis of the milk sold some years ago showed an average dilution with 33 per cent. of water. The State inspector found 12 per cent. water added and 20 per cent. of cream removed, the fraud amounting to over $10,000 a day. The results

in St. Louis, Chicago, and elsewhere were similar, and indicated the desirability of stringent laws to protect the pocket of the consumer, but when we remember the frightful infantile mortality, and the fact that the speaker has recently presented his conclusions, based upon 195 epidemics of typhoid fever, 99 of scarlet fever and 30 of diphtheria and that 52 of these outbreaks occurred in this country since 1882, we see at once that the milk traffic should be under strict sanitary control.

Laws Regulating the Sale of Drugs and Poisons.—Forty-two States and Territories have enacted laws to regulate the sale of poisons, but a careful study shows that they should be amended, and greater restriction placed on the sale of poisons generally. A recent investigation by a committee of the Medical and Surgical Society into the extent of the opium and drug habit in the District of Columbia developed some interesting facts, and led to the conclusion that one class of subjects have developed the opium habit by the use of the milder preparation of opium and some of the various proprietary or secret remedies commonly employed as domestic remedies, such as paregoric, McMunn's elixir, chlorodyne, blackdrop, soothing syrup, diarrhea mixtures, pain-killers, etc. It is clearly the duty of the State to close opium dens and restrict the sale of poisons, and in regard to the sale of patent and proprietary medicines containing poisonous drugs, the contents should be expressed on the label and the word poison added.

Patent and Proprietary Medicines.—By the term patient medicine, as properly employed in this country, England and Europe generally, it must be understood that the composition is known and can be seen at the patent office. The proprietary medicine is a secret preparation protected by a trade mark in this country, and hence preferred by the owner, but both are vaguely termed by the public patent medicines. Up to December 10, 1900, the United States Patent Office had issued patents on the following: disinfectants, 321; extracts, 250; hair dyes and tonics, 48; insecticides, 180; internal remedies, 376; plasters, 56; topical remedies, 371; veterinary, 78. Trade marks: drugs and chemicals, 319; medical compounds, 5,074, and increasing at the rate of about 250 a year.

The proprietary medicines are subject to the control of the State authorities, and if containing alcohol in sufficient quantity to be intoxicants are subject to internal revenue laws; but, so far as my knowledge extends, little or nothing has been done in this country and in England to control the sale of secret remedies.

Industrial Hygiene.—The relations of occupation to health and life were studied as early as 1700 by Ramazzini, an Italian physician, and since then numerous monographs have appeared. We know to-day that persons habitually engaged in hard work, especially in factories and indoors, present a higher mortality than persons more favorably situated, and that the character of occupations influences, to a great extent, not only the average expectation of life, but also the prevalence of certain diseases. For all these reasons the laboring classes need special protection, and in order to render this efficient, it must be provided for by the enactment and enforcement of suitable laws. The first law as regards safety and sanitation was enacted in Massachusetts in 1877, since which time, from information kindly furnished by the Hon. Carroll D. Wright, of the U. S. Department of Labor, thirty-two States have enacted similar laws, including legislation requiring seats to be furnished saleswomen in stores and shops.

Sanitary Dwellings for Wage-Earners.—No field affords better opportunity for philanthropic work than the erection of sanitary homes for wage-earners at reasonable rentals, the encouragement of cookery schools, the establishment of sanitary lodgings, model eating-houses and other betterments of industrial conditions.

Rural Hygiene.—When we consider the fact that over 70 per cent. of our population reside in rural districts, that the "bone and sinew" of these are engaged in agricultural pursuits, and that they do not enjoy the benefits of enforced sanitation by local health boards, we see at once the desirability of the family physician extending useful suggestions on healthful building sites and homes, disposal of house wastes, the importance of a pure water-supply, wholesome and properly cooked food, etc. As it is now, the diet is faulty, especially the hot biscuits, greasy fried dishes, while wells and privies are often dangerous neighbors. The undue prevalence of typhoid fever in rural districts could be materially checked by disinfecting the stools with three times the volume of boiling water and the adoption of the earth-closet system. This is all the more important since infection is often spread through the milk-supply, and many of our urban population contract disease in the country during the summer months. While prompt disinfection of the excreta is the only rational method, we should also make an effort to get rid of the flies by prompt disposal of the horse manure in which they breed, the abandonment of open privies and surface pollution, removal of garbage and other fly-breeding matter.

School Hygiene.—During the year ending June 30, 1900, there were 15,341,220 children enrolled in the common schools of our country. When we consider that the mental and physical vigor of a nation depends largely on the environments of childhood and youth, it seems strange that up to within forty years little or no attention should have been paid to the hygiene of schools. The occurrence of so-called school diseases is not surprising when we reflect that children, on beginning school, enter upon a new life and environment. Up to this time they have been allowed to run and play in the open air, exercise the body and senses, without restraint, but now without a period of transition they are obliged to remain for several hours a day in close and

sometimes insanitary school-rooms, taxing their minds and straining their eyes for near objects. Experience teaches and statistics confirm the conclusion that quite a number of children suffer from certain physical defects and diseases, which, because rarely observed before the school period, may be justly attributed the school environments. Among the most common of these affections are myopia, lateral curvature of the spine, dyspepsia, anemia, muscular debility, headache and nose-bleed, nervous affections and tuberculosis.

Smallpox and Compulsory Vaccination.—In this connection, attention is invited to the undue prevalence of smallpox in the United States; the total number of cases reported to the U. S. Marine Hospital Service during the past fall and winter, up to March 20, was 11,964, as compared with 7,279 cases for the corresponding period of the preceding year, and it is doubtless due to neglect in vaccination. Dr. Abbott estimates the vaccinated portion of the inhabitants of the United States at not far from 90 per cent., and the revaccinated portion at probably 50 per cent. With the introduction of glycerinated animal lymph every vestige of prejudice against vaccination should cease, and compulsory laws should be enacted in every State, so that smallpox here, as in the Germany army, may become practically unknown.

Venereal Diseases.—A careful perusal of recent literature on the subject of venereal diseases should stimulate our efforts in the prevention of diseases, which affect not only the offender, but innocent wives, the offspring and not infrequently even the medical attendant. According to Fournier, one-seventh of the population of Paris is syphilitic, and Morrow, from statistics gathered in New York, believes it is quite possible that Fournier's figures, with some modification, may apply to New York. Neisser holds that gonorrhea is, with the exception of perhaps measles, the most widespread of all diseases. Other German authorities have computed that fully three-quarters of the adult male population and one-sixth or more of the adult females have contracted gonorrhea; that 80 per cent. of all deaths from disease of the uterus and its adnexa are of gonorrheal origin, while blenorrhea neonatorum contributes a contingent to our asylums for the blind estimated at from 10 to 20 per cent.—from 40 to 60 per cent. before the Credé method was instituted—not to mention the destructive effects on the procreative functions. Dr. S. M. Burnett, of Georgetown University, believes that 15,000 of the 50,000 blind persons in the United States lost their sight from this cause, which according to his calculation involves a financial loss to the commonwealth of seven and one-half millions annually.

The measures which have been proposed for the control of the social evil and the prevention of its consequences are numerous enough, but not so easy of practical application. On the whole I believe the remedy lies in public education, and the task as usual falls on the medical profession, especially the trusted family physician. Public lecturers on the purity of man commit a serious mistake, however, when they picture the consequences of the social evil, without offering a suitable remedy. We should make a strong plea in favor of continence, and tell our young men that while the sexual passion is very strong it can be accelerated or delayed, excited or lowered by the influence of the will. We should assure them that by the cultivation of pure thought, removal of temptation, normal, mental and vigorous physical exercise, continence may not only become possible, but easy.

The Management and Control of Infectious Diseases.—It is the field of infectious diseases where preventive medicine has and doubtless will continue to achieve its greatest triumphs, and there is ample room, when we consider that during the census year of 1890 there were not less than 102,199 deaths from consumption, 74,496 from pneumonia, 74,711 from diarrheal diseases, 41,677 from diphtheria, and 25,058 from typhoid fever.

The eradication of preventable diseases is the highest aim of scientific medicine to-day. The public should be made familiar with the nature and causes of infectious diseases, and be taught that many are a source of danger, against which it is entitled to be warned by proper notification through the health officer. This notification should be made compulsory in cholera, yellow fever, smallpox, chicken-pox, typhus and typhoid fever, diphtheria and membranous croup, scarlet fever, tuberculosis, cerebrospinal meningitis, leprosy, glanders, bubonic plague, whooping-cough and measles.

Disinfection.—Scientific disinfection had its inception with the labors of Koch and Sternberg some twenty years ago. Although, as we have seen, certain physical and chemical agents were used empirically for ages, now we know from laboratory experiments that they are effective, because they destroy the vitality of the germs. We also know that, in most of the contagious diseases, the infective matter is given off by the patient chiefly through the secretions and excretions, and it is evident that disinfection to be of value must be directed to these and all the media with which the patient has come in contact.

If Certain Diseases Are Preventable, Why Are They Not Prevented?—My answer is that while every scientific physician familiar with biologic research knows full well that if the methods of prevention recommended by sanitarians, including the prompt disinfection of the dejecta of every typhoid fever patient, the expectoration and excretions of diphtheritic and tuberculous patients, for example, were adopted, these diseases would be reduced to a minimum and probably eradicated in the course of a few years. Nor are we responsible for the fact that so many of our States still permit every charlatan to practise one of the most difficult and responsible of all professions without a uniform and rigid sys-

tem of examination. However, we owe it to ourselves and to humanity to take positive steps in behalf of higher medical education and laws regulating the practice of medicine. So long as we permit the existence of irregular and incompetent practitioners, so long will the public be deceived and will we be obliged to compete with incompetent men, and so long as we tolerate the exponents of so-called "Christian Science," osteopathy, and other quacks, infectious diseases will be spread as the result of ignorance and neglect.

Forecast of the Result of the Census Work upon the Mortality Statistics.—Notwithstanding these and other disadvantages in the way of defective sanitary legislation, the American medical profession has reason to be proud of its work in the century's progress of hygiene and preventive medicine. It may be truly said that every hospital or other medical charity owes its foundation and success to the activities of the medical profession. Nay, every law inscribed on the statute books, in the interest of public health in this and other countries is the work of our noble profession. Acting upon the lofty principle that the education and betterment of the people in sanitation is not less humane than the healing of the sick, the American medical profession has filled the measures of its philanthropy by advocating laws to "regulate the health and physical well-being of communities," and thereby lessen its own income, but the results obtained during the last ten years are sufficient recompense. By the courtesy of Mr. Wm. A. King, Chief Statistician of the U. S. Census Bureau, I am enabled to give you a forecast of the result of the work upon the mortality statistics at the close of the century:

The mortality returns for the twelfth census, which relate to the year beginning June 1, 1899, and ending May 31, 1900, have not yet been tabulated in full, but sufficient progress has been made to permit a comparison of the preliminary results with the figures for 1899 for a portion of the country.

Considering these results for these States in which the returns were secured from registration records in both 1899 and 1900, there appears to have been an absolute decrease in the general death-rate of about 1.5 per 1,000 of population. This decrease seems to be most marked in the rates due to scarlet fever, whooping-cough, diphtheria and croup (combined), typhoid fever, malarial fever, consumption, diarrheal diseases, and diseases of the nervous system, the decrease in the mortality from diphtheria and croup amounting to more than 50 per cent. On the other hand, the rates due to carcinoma and tumor (combined), Bright's disease, heart disease and dropsy (combined), and pneumonia are apparently greater than in 1899, the increase being most marked in case of Bright's disease, carcinoma and tumor, and pneumonia.

The death-rate by age periods in the registration States has not yet been computed as the population figures are not yet available, but the effect of the decrease in the rates due to the causes specified is shown by a decrease in the proportion of deaths occurring at each period up to 30 years.

The results in the decreased rate of diphtheria, croup, scarlet fever, typhoid fever, whooping-cough, consumption, malarial fever and diarrheal diseases are the direct outcome of preventive medicine and are as gratifying as they are striking. We note with regret the increased rate in Bright's disease, heart disease, dropsy and pneumonia, and may well pause to inquire whether our ever-increasing "National Drink Bill," averaging 17.68 gallons per capita, may not be a factor in the development of these diseases, especially since there is reason to believe that the habitual and immoderate use of alcohol, apart from increasing the connective tissue and causing cirrhosis, also produces fatty degeneration, especially of the heart, liver and arterial coats, probably because it promotes the conversion of albuminoids into fats.

Without wishing to underrate the brilliant achievements in surgery of the brain, stomach, intestines, liver, gall-bladder and other abdominal organs, and even wounds of the human heart which have been successfully sutured in four of the nine cases reported, what after all are the ultimate benefits compared with the results obtained by improved methods in sanitation? It appears that the universal application of sanitary laws often robs them of their human interest, where the opposite should be the natural effect.

Since our knowledge of the nature of infectious diseases has been more and more defined, scientific methods for their prevention have been applied. We have learned, too, that in addition to the germ there must be a suitable soil for its proliferation and that sanitation will not only destroy the environments for its development without the body, but also place the system in the best possible condition to resist its toxic action.

The application of this knowledge has saved millions of lives besides an incalculable amount of human suffering and distress, not to mention the economic aspect of the question which should appeal to the most mercenary.

To the solution of this problem, the labors of Salmon and Smith, Sternberg, Welch, Osler, Councilman, Reed and other Americans engaged in experimental medicine have contributed their full share. Progress has crowned our past, we will not retrograde. Let our conduct raise no blush on the cheek of posterity. Let us hand in hand with heart and mind join in promoting the welfare of American medicine, until she has reached the proudest pinnacle in the world of science, until she has become the fountain-head of knowledge for the benefit of mankind. Then when at last we are called upon to pass through the portals beyond, Minerva Medica, in her sweeping robes of state, will proudly but reverently present us to the Supreme Healer of the Universe as types of the true physician.

MEDICAL PROGRESS.

Ovarian Secretion.—Referring to the effect of double ovariotomy and the influence of the ovarian internal secretion, W. E. Dixon (*Practitioner*, May, 1901) believes that the presence of ovarian tissue in the body, however small in amount, is sufficient to prevent the distressing symptoms which frequently follow complete extirpation. Even transplanted ovaries are sometimes able to prevent the induced menopause which is probably certain to occur if the ovaries are entirely removed. The administration of ovarian tissue by mouth exerts a beneficial influence on patients in whom menstruation has ceased in consequence of disease or complete ovariotomy. It has a direct effect upon metabolism as shown by the increase in weight due to the deposition of fat and the diminished excretion of P_2O_5. Evidence points to the theory that the ovary furnishes an internal secretion which favors catabolic changes.

Saline Treatment of Dysentery.—W. J. Buchanan (*British Med. Jour.*, April 13, 1901) presents a continued report of 855 cases of acute dysentery with but nine deaths—a little over 1 per cent. The solution used is as follows: Sodii sulphatis ʒi, aquæ forniculi ad. ʒi. One dram four to eight times a day. It is important that the stools be inspected daily, the saline being continued till every trace of blood and mucus has disappeared. Although this treatment has been severely criticised by the Medical Corps in South Africa as being too painful for practical use, Buchanan states that this is not the case if intelligent care be used in its exhibition. He states further that the saline is suited to the acute form only and should never be tried in the chronic. The diet in the Bengal Hospital consists largely of rice-water, boiled milk and tyre. This diet, together with daily inspection of the stools, is of paramount importance.

Adrenalin.—Emil Mayer (*Phila. Med. Jour.*, Apr. 27, 1901) describes the characteristics of this drug and its actions, and presents a table showing the results obtained from its use in thirty-five cases. From his clinical experience with adrenalin, the active principle of the suprarenal gland, the writer formulates the following conclusions: (1) Adrenalin solutions supply every indication in rhinological practice for which the aqueous solutions of the extract have been hitherto applied; (2) they can be used in sterile form; (3) they remain unchanged for a long time; (4) a solution of 1 to 1,000 is very strong and is all sufficient for operative cases, and 1 to 5,000 or 1 to 10,000 for every purpose of local medication; (5) they may be safely applied to persons of every age and of either sex. Mayer believes that in the isolation of the blood-pressure-raising principle of the suprarenal glands we are confronting an epoch-making discovery, and that with the discovery in the near future of the active principles of other animal substances, organotherapy will derive a new impetus and an exactitude in administration which will give these remedies a new power in our hands.

Mixed Narcosis.—H. Braun (*Münch. med. Woch.*, May 14, 1901) draws attention to the greater safety of ether-chloroform mixtures over pure chloroform and to the inaccuracies experienced in giving them with the usual masks. He recommends a specially constructed apparatus, which allows air to pass through both chloroform and ether, the amount of each being regulated by several levers. The anesthesia is induced with a mixture of both vapors, a bulb being pressed synchronously with the inspirations. As soon as complete relaxation is established, the lid-reflex still being present, the narcosis is continued with pure ether. If at any time the respirations should become too shallow, the ether should not be pushed, but chloroform added. In the majority of cases, the period of toleration was reached in 6-8 minutes and but small quantities were found necessary.

Malignant Syphilis.—As characteristic of the malignant form of syphilis D. Lochte (*Monatshft. f. prakt. Dermatolog.*, May 15, 1901) mentions the early appearance of numerous ulcerations over the entire body, loss of weight, fever and inefficiency of the usual antisyphilitic remedies. Frequently generalized lymphadenitis is absent and the skin generally shows the most extensive lesions, which very early take on the appearance of tertiary change. Although mercury is often powerless, iodide of potash is frequently well borne: in most cases, however, the best results will be obtained from a preliminary course of tonics such as iron and cinchona. Renewed attempts with the iodides may then be made; if a tolerance is not established, iodothyrin may be resorted to. The causes of malignancy of syphilis in certain patients is not very clear, but certain diseases, as alcoholism, tuberculosis, scrofulosis and diabetes, are mentioned as lowering the resistance of the tissues to syphilitic infection.

Hand Disinfection.—P. G. Unna (*Monatshft. f. prakt. Dermatol.*, May 15, 1901) recommends the following method: the surgeon on the night before the operation scrubs his hands with soap and hot water and then applies an alcohol dressing covered with gutta-percha. The next morning, superfatted soap is employed and the hands then dried with a sterile towel. Immediately before the operation, the superfatted soap, which protects the crevices of the skin, is then washed off.

Action of Orchitic Extract.—Ancient Roman and Grecian history contains many allusions to the use of semen or testes to increase the vigor of wasting manhood. In modern history Brown-Séquard seems to have been the cause of a revival of the use of this method which had been neglected during the medieval years. Results have been most conflicting, but experiments have recently been made to determine the changes of

metabolism which occur after its administration. W. E. Dixon (*Practitioner*, May, 1901) finds that it is probably the nucleo-proteid portion which acts nominally as an internal secretion and produces a specific effect upon metabolism. When taken by mouth an immediate hyperleucocytosis is produced, and the excretion of P_2O_5 in the urine is increased, the increased excretion of P_2O_5 being in excess of that contained in the nucleo-proteid. When injected subcutaneously there is a prolonged hypoleucocytosis and the phosphoric acid excretion in the urine is diminished. Furthermore, the latter method has a direct effect upon the heart and peripheral circulation. The heart is slowed and the action becomes more feeble and, mainly as a result of this effect, the blood pressure falls. There is also a dilatation of the peripheral blood vessels. The clinical value of this remedy is still unknown, although it has been recommended for various diseases, especially of the nervous system, by most able authorities.

Treatment of Meningitis.—Depending upon the age of the patient and the severity of the case, F. Daxenberger (*Klein. therap. Woch.*, May 12, 1901) has used 2-3 grams (30-45 grs.) of Credé's ointment twice daily up to a total of 10-20 grams (150-300 grs.) rubbed into the skin of the head or neck in cases of acute meningitis with some remarkable cures. At least fifteen minutes should be spent in the inunction and a resulting dermatitis is no contra-indication.

Lumbar Puncture in Persistent Uremic Headache.—In a case of uremia presenting albuminuria, high arterial tension and cardiac hypertrophy, Marie and Guillian (*La Méd. Moderne*, May 8, 1901) resorted to lumbar puncture for the relief of the violent and persistent headache, ordinary treatment having proven ineffectual. Six c.c. of cerebrospinal fluid were removed. The relief of excessive tension by this means was followed within two hours by a disappearance of the headache, and the symptom did not return for two days. The authors hold that there is a certain analogy between the hypertension of the cerebrospinal fluid in nervous uremia and that which is known to exist in cases of brain tumor. The indication for lumbar puncture in uremia is the continued presence of severe headache in spite of rigorous treatment of the underlying cause. It should not be resorted to, however, until analgesics have failed.

Antistreptococcus Serum in Puerperal Infection.—Ludwig Knapp (*Prager med. Woch.*, May 9, 1901) injects as first dose 10 c.c.; when negative result follows the dose is repeated after twelve hours, and a third dose is given twelve hours later if necessary. It cannot be said that this treatment has yet been satisfactory. The results have been either doubtful or absolutely negative.

Causes and Treatment of Movable Kidney.—M. L. Harris (*Jour. Amer. Med. Assoc.*, June 1, 1901) has made careful measurements in two hundred cases, including men, women and children, and argues that the essential cause of movable kidney lies in a particular body form whose chief characteristics are a marked contraction of the lower end of the middle zone of the body, with a diminution in the capacity of this portion of the body cavity. This diminution in the capacity of the middle zone depresses the kidney so that the constricted outlet of the zone comes above the center of the organ; such acts as coughing, straining, lifting, flexions of the body, etc., which tend to adduct the lower ribs, press on the upper pole of the kidney and crowd it still further downward. Continued repetition of these influences produces movable kidneys. In fixing a movable kidney, it is best to fix it low down, where it will not again be subjected to the influences which originally caused its descent.

Acetopyrin in Rheumatism.—This drug is recommended by Capitan (*La Méd. Moderne*, May 1, 1901) in cases calling for the combined therapeutic action of salicylic acid and antipyrin. It appears to have no objectionable action on the stomach. In forty cases of rheumatism treated by Bolognerie, rapid effects were produced by the administration of two to three grams daily, in divided doses. In rare instances some depression resulted, but no case of collapse is recorded. Temperature is said to be reduced at least 1° C. within an hour after the administration of a single dose.

Diagnosis and Surgical Treatment of Renal Diseases.—According to F. Tilden Brown (*Boston Med. and Surg. Jour.*, May 30, 1901) smegma bacillus leads to confusion in diagnosis; it is excluded by collecting urine by catheter from the bladder. In doubtful cases animal inoculation must be resorted to. Tubercle bacilli having been found in the urine, cystiscopic ureteral examination will fix the location of the lesion in the bladder or kidneys. In some cases the lesion is not in open communication with the urinary channels, and symptomatic diagnosis must be made. Lumbar pain may occur early. Frequency of urination indicates involvement of the lower segment of the ureter. The principal objective symptoms are enlarged and tender kidney; pyuria and hematuria, diurnal variation in temperature, loss of color and weight, reaction to tuberculin, tubercle bacilli in urine. The value of tube cultures is chiefly in the demonstration of the presence of other pathogenic microorganisms. Treatment consists of nephrectomy.

How to Treat Muscular and Joint Sprains.—Haldor Sneve (*Jour. Amer. Med. Assoc.*, June 1, 1901) points out that mere immobilization of muscles is not equivalent to rest; the muscles remain in a state of tonic contraction and can best be treated by passive motion from the beginning and active exercise later. Plaster casts are only to be used where it is impossible otherwise to maintain a proper position of the joint, as in some cases complicated with fracture. Ice over a wet cloth is useful during the first few hours; hot fomentations later where stimulation is needed. For strains the best treatment is the

counterirritation of static electricity in conjunction with massage. The best treatment for sprains is the ambulatory treatment with massage.

Lobar Pneumonia "Cured" by Diphtheria Antitoxin.—Following the suggestions of Talamon and Capitan, Negel (*La Méd. Moderne,* May 1, 1901) treated a case of frank lobar pneumonia in a man, fifty-eight years of age, by the injection of 20 c. c. of antidiphtheritic serum. This injection was given on the day the physical signs were detected, two days after the patient entered the hospital with symptoms of a common cold. The dyspnea at this time was marked; there was pronounced dulness over three-fourths of the right lung, and pronounced tubular breathing; temperature 39° C. The following day numerous râles were heard, temperature was 38° C., but the patient was still feeble. The serum injection was repeated—20 c.c. Twenty-four hours later temperature was 37.8° C. Crepitant râles were numerous, and resolution proceeded from this time without interruption.

Use of Sulphur Waters in Endometritis.—Natural and artificial waters containing H_2S have been employed with success in the treatment of chronic endometritis by Perrier (*Jour. de Méd. de Paris,* May 12, 1901). Associated lesions of the adnexa do not contra-indicate this treatment, but are even ameliorated by it. Caution is advised in cases having cardiac disease, advanced tuberculosis, uterine fibroma or general nervous irritability. Perrier believes that sulphur irrigations give more certain and more lasting results than curettage. They have been found useful, both in chronic catarrhal or purulent endometritis and in hemorrhagic or decidual cases.

Muscular Action of Arteries.—In commenting upon Dr. Daland's paper on arterial spasm A. H. Smith (*N. Y. Med. Jour.,* June 1, 1901) says that too little attention is paid to the changes which occur in the muscular layers of the blood-vessels in cases of arteriosclerosis. Physiologically the whole arterial tree, to its minutest branches, is only a continuation of the left ventricle and is therefore a muscular organ. There is a positive muscular action following behind the volume of blood and it is caused by the stimulating action of the distention of the blood-vessel by the passing wave of blood. The condition of arterial spasm, therefore, not only increases the work of the heart directly, but also cripples the heart by depriving it of the aid it should have from the rhythmic muscular action of the arteries.

Theories of Inheritance.—Although medical men are continuously inquiring of their patients in regard to inherited conditions and diseases, they pay little attention to the theories which have been advanced relative to the method of transmission of such maladies. For many years Weissmann's theory that acquired characteristics were not transmitted to offspring held complete sway and was very generally accepted. Recently numerous authorities have been disposed to doubt the validity of such an assumption and J. G. Adami (*N. Y. Med Jour.,* June 1, 1901), after showing the difficulties in the way of accepting Weissmann's theory, suggests another seemingly reasonable cause for variation. According to Weissmann, the germ cell is made up of a vast number of ancestral plasms or "ids" derived from a long line of progenitors and as the ids in two fertilized ova are not identical, as the same series of ancestors do not contribute to the germ plasm of the two, so it is that individual variation originates. As segmentation goes on germ-cells are soon set aside and a certain series of ids passes into each cell as it becomes differentiated, the germ-cells receiving the full complement of all the ids. Wilson and Morgan have recently proven, however, that in a segmenting ovum if the cells be shaken apart at the two-, four-, eight-, or even sixteen-cell stage, each separated cell can be found capable of developing into an entire, if dwarfed, individual. Driesch suggests that the variation in structure of different tissues must be "a function of their relative position." Medical men are frequently confronted with conditions which are evidently inherited from ancestors that acquired those characteristics. In bacteriology, where generations are created so rapidly and hence the effect of external influences can be more fully and easily watched, there seems to be little doubt remaining that characteristics of a particular germ can be radically changed by environment and that this change is gradually transmitted to the progeny. The author suggests what he calls the "side-chain" theory of inheritance to explain present observations. He pictures the primitive idoplasm as composed of a mass of material each molecule of which is formed of a central ring to which there can be attached side-chains from which sundry side-chains can be detached without the central ring being destroyed. Thus, we suppose that there is a central basal substance to which become linked, more or less permanently, or more or less temporarily, those other secondary substances which, not in themselves protoplasmic, modify the constitution of the protoplasm as a whole. Two forces determine the structure of every cell in the body: (1) The previous influences acting upon its idioplasm and causing it to be of a particular chemical constitution, and (2) the position in which the cell finds itself in the body. The germ-cells naturally undergo very little change, but in terms of this theory inheritance depends upon the chemical constitution of the idioplasm, and variation, whether slight or extensive and leading to the formation of species, is the expression of modification brought about by environment.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 8, 1901.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

THE American Medical Association assembled for its fifty-second annual meeting on Tuesday morning, June 4, 1901. Everything was auspicious for a most successful gathering. A very large delegation came by special train from New York, many Philadelphians were present and for a Western meeting the present session had a representative character that promises well for the future of the Association. With the next meeting at Saratoga to arouse still further enthusiasm there is no doubt that conditions are all that can be desired. Important changes in the organization of the Association were affected at this meeting that give every reason to hope for more perfect union for every worthy purpose.

The address of the President, Dr. Reed, was worthy of the opening of the new century. There was a broad grasp of the interests of the medical profession at large in this country that stamps the retiring President as a man of striking liberality of view. He has studied the needs of the Association deeply and has a practical remedy to suggest for many evils only too manifest. His expression with regard to the code and the unfortunate trouble over it was a masterpiece of good sense and impartial judgment. The President of the Association publicly recognized the good that had been done by the conduct of New York medical men, although it cost them their membership in the Association. He pointed out that with the beginning century so many scientific problems require solution and so many of the best interests of the profession are at stake, harmony on the basis of the most good out of the brotherhood must be achieved.

Among the practical features of the present meeting the discusssion in the Medical Section have been especially noteworthy. Blood conditions came in for the share of attention that recent advances in blood work demands. In the discussion of these disorders forty cases of pernicious anemia were reported from Johns Hopkins Hospital and many striking facts were brought out. The great preponderence of male sufferers from the disease is especially noticeable. The low place that such supposedly active causal factors as worry and pregnancy take was a matter of surprise considering how much the etiological significance of such conditions has been generally conceded. The question of oral sepsis as a cause of the disease had to be touched on. Hunter's theory has at least called attention to how often hospital patients have septic conditions in their mouths, although the presence of such form of germs is only a coincidence not a causal element in pernicious anemia.

The discussion on appendicitis brought out nothing new, except, perhaps, the fact that medical men generally now frankly concede the surgical nature of the disease in almost every stage. In this medical opinion has changed very much for the better in the last five years. The new century opens with the surgeon in the saddle on all appendicitis questions.

New light was thrown on the difficult problem of cirrhosis of the liver and some eminently suggestive remarks were made in the discussion. The question of the old traditional biliousness as a possible preliminary of cirrhosis of the liver is startling enough. Its greater frequency than has been generally supposed is also a suggestive reflection of the trend of modern medical thought.

The meeting has been a decided success. St. Paul may well be proud of the magnificent welcome she extended and the 2,000 medical visitors will not soon forget the pleasant time spent in the capital of the Northwest.

A NEW INSTITUTION FOR MEDICAL RESEARCH.

Newer developments in America have been leading more and more toward realizations in the field of scientific medicine. Conditions for the pursuit of higher research along medical lines cannot be said, up to the present, to have been overencouraging, but recent indications suggest possibilities in this direction whose outcome can be but tentatively estimated. A more intelligent appreciation of the needs along these lines by both the medical profession and broad-minded men generally justifies a hopeful forecast for the future.

An enterprise of extraordinary value and promise which will do much to further medical research work in this country is initiated by a corporation (Rockefeller Institute for Medical Research) which starts with a gift of $200,000 from Mr. John D. Rockefeller. Its headquarters will be in New York City. The object of this new creation is to furnish facilities for original study of medical problems, bearing more especially on those questions whose answer should be of practical application in the prophylaxis and treatment of disease. Judging from information at hand, it seems probable that emphasis will be laid upon the prophylactic side which after all is the most logical aim of practical medical research; and, with this view in mind, it has already been suggested that one of the problems whose solution would for the present prove of even greater benefit to humanity than many other studies is the relation of milk-supply to gastro-enteric maladies of children. Experiments will be made in the laboratories of several leading universities, and one person will be sent to Europe to report upon the results of similar studies there.

But this represents only one of the features of the plan in view. Definite problems will be taken up, and as the work develops it is hoped that a permanent staff of competent workers will be organized.

Looking at it from a still broader point of view, this institution will probably fulfil the desires of a large class of advanced workers who have been unable to pursue original investigation to the best advantage. Many a medical man has felt the assurance that he might make contributions to medical science of lasting value if he could only be relieved of the exhausting work of his regular routine and could devote all of his energies to advanced study and research with suitable support and congenial entourage. The new institution is expressly designed to meet this difficulty.

Remarkably good sense is, in our opinion, shown in the decision to "feel one's way" toward the ultimate realizations of the institution rather than start with a completely formulated scheme which of necessity would have to be revised as the indications suggested. It is assumed that the $200,000 gift is only a beginning, and that Mr. Rockefeller will be ready to provide the necessary buildings when the time is opportune and furnish whatever further funds may be required.

Under the management of a Board of Directors so admirably selected there can be no lack of confidence in the practical and beneficent results of this rich endowment.

THE ARMY CANTEEN.

Much adverse comment is certain to result from an expression by any important society of physicians of disapproval of the law now in force abolishing the canteen in the army of the United States: yet within the profession the propriety of joining vigorously in a memorial to Congress that shall set forth the desirability of re-establishing this institution must be readily recognized. The argument is neither long nor involved. The life work of the American physician is the care of the physical well-being of the American people, and when any question arises regarding a cause of action that will materially affect the health of a large body of our citizens, it is not only his privilege, but his duty to give expression to a positive opinion. That the abolishing of the canteen has seriously affected, and for the worse, the bodily soundness of a large number of people there can be little doubt. The testimony of the men in a position to observe, men of high standing, under no stress to misrepresent facts, for whom, indeed, the training of a life time has been that of the accurate observation and report of facts, is positive on that point. Their testimony is the more readily accredited in that it agree with the universally accepted narratives of past experiences. It has been a common experience for a prolonged campaign to bear in its train a wave of venereal infection that the disbanding of the armies has caused to roll through the

length and breadth of the unfortunate nation for which they have fought. There are psychological as well as practical reasons why the soldier in time of war is both more indulgent of his sexual desires and less painstaking in the effort to avoid infection than the civilian, and similar influences operate to render the resorts of the camp-followers more deadly than the bawdy houses of the city, and as frequently as these facts have been noted has come the further observation that the drinking-places outside the camp lines have been the feeders for houses of assignation.

There is this double plea for the canteen from the medical standpoint. By its tendency it keeps the soldier within the camp, providing him with a mild stimulant of pure brew, instead of driving him outside the lines for the satisfying of that craving which arises from the nature of his calling, it preserves his system from the shock of the vile concoctions which are sure to be foisted upon him when the purveyors to his appetite know he can get nothing else, and saves him also from venereal infection by failing to make fierce assaults on his moral stamina and natural self respect. For, so repulsive are the great majority of female hangers-on at the outskirts of a military camp, that the lowest grade of the American soldier must needs have his senses dulled by something far more potent than canteen beer, ere he can bring himself to intimate association with them.

There was a strong representation of the medical branch of the army at the meeting of the American Medical Association at St. Paul this week. Unanimously and emphatically these men pleaded for the formal expression by the Association of a protest against the present law. Neither their motives, nor the statistics they gave in wealth of detail, were to be questioned. What action the Association will take in this matter is not known at this writing, but, whatever it is, we trust it will be taken in the full understanding that it will be welcomed and weighed and respected.

THE VALUE OF EXAGGERATION.

MOST ably has the subject of the doctor's fee been treated by Roberts (*Philadelphia Med. Journal*, May 11, 1901) and most thoroughly has he exposed many of the unethical and dishonest method by which it is increased. He scathingly denounces the system adopted by some consultants of offering commissions for patients and dividing fees received from them with the sender. The furnishing of testimonials to manufacturers of drugs for pecuniary or other recompense is justly condemned. The overcharging of the wealthy on the ground that they can afford to pay and of the estates of deceased patients, because the dead cannot complain, comes in for a share of denunciation, while the surgeon who will wait with the patient anesthetized and upon the table until his fee is paid is given the notoriety which he deserves.

The subject is decidedly unpleasant. Far more agreeable is it to discuss the effects of the abuse of alcohol by others, and to point out the resemblance between the so-called Christian Scientist and the guinea-pig on the ground that the latter is not a pig and that it did not come from Guinea. It is hard for a member of that profession which is composed of men whose relations to others most demand justice and a high moral sense to acknowledge the shortcomings of the fraternity. The family skeleton in the closet is not a congenial companion and the one exposed to view by Roberts is not the only one which the medical profession possesses. Advertising is one which has been given considerable notoriety. But what of exaggeration for the sake of impressing an actual or prospective patient? It is certainly one of the most common and most successful methods of enlarging a practice, but he must be careful indeed who escapes detection by others of the profession. We do not refer to self-glorification at society meetings, references to the extent of one's practice, or to others as the younger men; not to the publication of articles describing unique methods of palpating the impossible, of performing a whole series of operations through a microscopic incision of stated dimensions; not to seeking notoriety by receptions given to persons of note, or by newspaper interviews in which the speaker is more emphasized than the subject. These are merely phases of the advertising skeleton, showing various degrees of taste.

The form of exaggeration which is an indication not merely of lack of taste, but of dishonesty, appears in many shades. One of its best known examples is that of the physician who is invariably called just in time to prevent a threatened pneumonia or to save the patient's life; the man who diagnoses every case of bronchitis as pneu-

monia and claims that he has never had a death from the latter disease. Closely allied is the surgeon who with equal frequency dwells upon the seriousness of every case and every operation, however trivial, and lives upon the reputation acquired by the brilliant results he attains in spite of his dark prognoses. He is usually not one who is diffident in regard to mentioning such results or the number of his operations. The patient is usually pleased by the idea that he is a most unusual or serious case and is the last to suspect exaggeration. A well-known surgeon called to treat a case, apparently a limited cellulitis of the ankle, pronounces it "blood poisoning" and evacuates a small amount of pus. At a second visit a similar spot appears upon the anterior aspect of the ankle and is also relieved by a slight incision. The patient is surprised that he feels so well with so serious a difficulty, but is assured that it is nevertheless an ominous malady. After three weeks of treatment he is cured: he then publishes to his friends, lay and medical, the wonders of his case. His professional friends say nothing, but has their opinion of the well-known surgeon been improved, and are they the more likely to call him in consultation? Again a patient with chronic appendicitis, recovering from an exacerbation, is advised to wait until the interval and then be operated upon by his own surgeon in Boston. A surgeon who is as well known as he can make himself is called as consultant. Without a word to the attending physician he informs the patient and his family that his condition is serious and immediate operation is necessary. He is removed to the hospital where the surgeon operates, is kept in bed for twelve days and then operated upon after the attack has subsided. Incidentally suppuration of a clean case occurs, but this point is not exaggerated and is referred to as a slight oozing from the abdominal fat. Will he be called in consultation by those who know his name?

And concerning those whose statistics are manipulated; if such liberties with strict truth are not evident upon the face of their articles there are almost invariably enough witnesses to compare the published accounts with what they have seen. And of what advantage is it to minimize the dangers of a procedure which one advocates? Suppose that an operator publishes a long series of operations under lumbar anesthesia and claims that the inconveniences are insignificant, the headache following so slight as to be negligible. Investigation will undoubtedly show that morphine has failed to relieve the suffering which the injection of cocaine caused, and the reporter's reputation has suffered by inaccuracy.

The tendency to specialize has become so strong that it has been said that diseases of the umbilicus is the only field that has not been filled. Convalescence is evidently the specialty of some physicians, for it is well known that there are those whose daily visits rarely terminate until the patient, in self-defense, is obliged to assume the responsibility of deciding that a cure has been accomplished for some time.

Where competition is so keen as in New York and exaggeration is so common a bait for the patient, the fact that such procedures are not ethical will have little weight with those most concerned. But after all honesty is the best policy. Murder will out, and eventually many a dishonest act will work untold harm to its performer.

ECHOES AND NEWS.

NEW YORK.

Inquiry Concerning Tuberculosis in New York State.—Local health officers throughout the State have been requested by the State Department of Health to furnish a list of the number of persons afflicted with consumption in their respective localities. The present immediate purpose is not to require or obtain a personal registry of these cases, or to institute a system of sanitary inspection or isolation of consumptives, but to obtain with such accuracy as it is possible to do, a record of the number of persons in each municipality who, at this time are subjects of this disease; to learn the locality of the disease, its distribution and surroundings. This accumulation of data will be fundamental to more exact plans for control of the disease.

New Buildings for Rochester Hospital.—The State Commission in Lunacy has approved of plans for a new group of buildings at the Rochester State Hospital to cost about $230,000. This will afford additional accommodations for 500 patients.

New Appointments Medical School Columbia University.—Drs. Charles H. Peck, Warren S. Bickham, and Alfred S. Taylor were appointed assistants in surgery. The winners of the Jacob Harsen Prize this year are Charles Smith, Philip Van Ingen, and William Darrach.

A New Journal.—A copy of a new journal devoted to the interests of psychiatry has just arrived. It is called "The Journal of Mental Pathology," and is edited by Dr. Louise G. Robinovitch. On the staff of contributors

we notice some of the most distinguished men of medical science.

Gift to Medicine.—Mr. John D. Rockefeller has given $200,000 to found an institute for medical research, with its headquarters in New York City. It is generally believed that this will lead to a still more adequate endowment when the time comes to erect a permanent home for the work. The direction of the new institution has been entrusted to the following distinguished gentlemen: Dr. William H. Welch, of Johns Hopkins University; Dr. T. Mitchell Prudden, of Columbia College; Dr. L. E. Holt, of the same institution; Dr. C. A. Herter, of New York University and Bellevue Medical College; Dr. Theobald Smith, of Harvard; Dr. H. M. Biggs, of the New York City Board of Health, and Dr. Simon Flexner, of the University of Pennsylvania.

New Buildings for Loomis Sanitarium.—A new chapel and buildings at the Loomis Sanitarium in Liberty, N. Y., were dedicated last week. The chapel is the gift of Mrs. Loomis, in memory of her husband, Dr. Alfred Lee Loomis, after whom the sanitarium is named.

Health Authorities After Unclean Milkmen.—The health authorities of Flushing, L. I., are making a crusade against milkmen who are suspected of violating the sanitary laws. Thirty-two cases of alleged violations recently came up in the local court. It is alleged by the authorities that the cans used by these men were found in a dangerously unclean condition.

Smallpox in New York City.—Cases of smallpox continue to be reported to the Board of Health. Seventeen deaths occurred from the disease last week. Incoming vessels, especially those from Naples and other Italian ports, are being held in quarantine for precautionary reasons.

Home for Convalescent Patients.—On May 27th St. Eleanor's Home for Convalescent Patients, which is situated on a high hill between Scarsdale and Tuckahoe in Westchester County, was dedicated by Archbishop Corrigan. The home will be open to convalescent patients from the hospitals of New York, who can remain there in charge of doctors and nurses and enjoy the country air until they are cured.

CHICAGO.

Resignation of Dr. Futterer.—Dr. Gustav Fütterer, who for two years has been Professor of Pathology, at the Northwestern University Medical School, has resigned and his resignation has been accepted by the Trustees. As the school closes this week for the summer vacation, no immediate action will be taken in the matter of selecting a successor.

Commencement Exercises.—These exercises were held by the College of Physicians and Surgeons on May 20th. The graduates numbered 160. The Doctorate Address was delivered by Dr. Joseph M. Matthews, of Louisville, Kentucky. At the banquet of the Alumni Association of the College in the evening, Dr. Wm. Allen Pusey acted as toastmaster. President Draper, of the University of Illinois, responded to the toast "The University." The Rev. W. A. Burch made some remarks on "Physicians, by a Clergyman." Dr. Harold N. Moyer, of Rush Medical College, responded to the toast, "Our Friend, the Enemy." He commented on the equipment of Rush Medical College, as well as that of the College of Physicians and Surgeons, saying that both were incomplete. Dr. Alexander Hugh Ferguson spoke on "Failure and Success in Surgery."

Election of Dr. Fenger.—At the recent meeting of the Military Surgeons, held at St. Paul, Minn., Dr. Christian Fenger was elected honorary member of the Association.

Appointment of Dr. Dudley.—Dr. E. C. Dudley has been appointed a member of the Chicago Board of Education.

Election of Dr. Beck.—Dr. Joseph C. Beck has been elected Professor of Diseases of the Ear, Nose and Thoat, in the Chicago Eye, Ear, Nose and Throat College.

Appointments of Drs. Dickerman and Beard.—Drs. Charles H. Beard and Edward T. Dickerman have been appointed on the staff of the Illinois Charitable Eye and Ear Infirmary.

Donation by Marshall Field.—Marshall Field has given the Chicago Home for Incurables ten lots adjoining the ground now occupied by the home. This land is valued at between $40,000 and $50,000.

American Gynecological Society.—This Society has just closed its twenty-sixth annual meeting, it being one of the most interesting in its history. The papers were of a high scientific order and the discussions spirited. A very full report of the proceedings of this meeting will appear in a future issue of the MEDICAL NEWS.

Smallpox Situation.—The thing most dreaded by the Department of Health is a change in the type of the smallpox. If this should occur, serious results are inevitable. The disease has been so mild that the contagion must be spread to an unknown extent from cases that have not come under observation. No person who is not positive as to vaccinal protection can afford to postpone vaccination before the weather gets too hot for the operation, and before the disease changes to a malignant character.

Hospital Gift Refused.—It is said that the offer of two Swedish-Americans in San Francisco to give $25,000 each for the erection of a hospital in Lakeview, or other suitable location in Chicago, has been refused by the

Swedish Evangelical Mission Board unless the hospital is established in Bowmanville.

GENERAL.

Leprosy in the United States.—According to scientific investigations directed from Washington for several months, there are at least 275 cases of leprosy in the United States. That number have been reported, but it is thought probable that the real number is nearer a thousand. Seventy-four of the known cases are in New Orleans, chiefly among the Italian population. There are twenty-three in Minnesota, mostly among Scandinavians in the rural settlements. There are fifteen cases in North Dakota, and two in South Dakota, among the same people. So far as has been ascertained, there are none in Michigan or in Indiana; Chicago has five cases, New York six, Boston none. It is the intention of those who are compiling the figures to make a report to Congress, including such recommendations as may seem warranted. One recommendation will be for the erection of two large Government hospitals for lepers, one in the South and the other in the North. Eminent physicians have at different times been before committees of Congress in the interest of the erection of leper hospitals, but nothing came of these visits, the Government having no reliable data covering the prevalence of the disease.

American Laryngological Association.—The following officers for the next year were chosen: President, J. W. Farlow, of Boston; first vice-president, J. W. Gleitsman, of New York; second vice-president, D. Braden Kyle, of Philadelphia; secretary and treasurer, James E. Newcomb, of New York City; librarian, Joseph H. Bryan, of Washington; member of council, Henry L. Swain, of New Haven. Papers were read by Dr. Gleitsman, Dr. T. R. French, of Brooklyn; Dr. F. H. Bosworth, of New York; J. H. Goodale, of Boston; C. H. Knight, of New York; Carl Seiler, of Philadelphia; W. K. Simpson, of New York; Dr. A. W. Watson, of Philadelphia; Dr. Farlow and Dr. Wyatt Wingrave, of New York. It was voted to hold the next annual meeting in Boston about June 1, 1902.

The Military Surgeons' Convention.—The first session of this year's convention was held May 30th, at St. Paul, Minnesota. The convention was called to order by Brig. Gen. John F. Fulton of that city. Governor Van Sant, Mayor Smith, and Judge E. A. Jaggard delivered addresses of welcome. Dr. A. J. Stone, the President, delivered the annual address.

Increase in Vivisection.—The recent issue of a Parliamentary paper containing accounts of a number of experiments performed on living animals during the year 1900, under licenses, has raised the usual outcry from the anti-vivisectionists, who point to "thousands of tortured innocent dumb brutes," etc., but the report of the inspector under the Cruelty to Animals Act shows there is no ground for this complaint. The total number of licenses was 247, of which sixty-three did not perform experiments. The licenses were recommended by men of the highest scientific standing. The total experiments were 10,830, an increase of 2,370 over 1899. The appearance of the bubonic plague is responsible for part of this increase. George D. Thane, the inspector under the Cruelty to Animals Act, says: "It is of the greatest importance that this disease should be recognized at the earliest possible moment. This can only be done with certainty with the aid of inoculations into animals. Two new licenses, which were granted in 1900, expressly allow necessary experiments in localities where infection is apprehended."

No "Mental Therapeutics" in North Carolina.—The Secretary of State of North Carolina has refused to charter a new College of Science and Healing"—the first institution of the kind proposed in this State. In taking this position he is fortified by an opinion of the Attorney-General of North Carolina, and the terms of the law governing the issuing of licenses to practise medicine in this State.

New President of Johns Hopkins University.—Prof. Ira D. Remsen, who since the founding of the Johns Hopkins University in 1876 has occupied the chair of chemistry, will be the future President of this institution to succeed Dr. Daniel C. Gilman, resigned. This decision was reached by the trustees at a meeting held June 3d. Dr. Gilman's resignation will take effect this month. Prof. Remsen will enter upon his duties as President at the beginning of the academic year in September.

Mississippi Not Polluted.—In an exhaustive report filed with the State Board of Health last week Dr. John Long, professor of chemistry in Northwestern University, special investigator for the State, asserts that for a distance of forty-two miles north of St. Louis there is absolutely no trace of sewage in the waters of the Mississippi. Researches and chemical tests of waters of Illinois and Mississippi Rivers cover a period extending back before the drainage canal was opened, and show that the effect of the opening of the canal was harmless.

Cleveland's Smallpox Cases.—According to a dispatch from Toledo a sensation has been sprung in Ohio over a public statement by the Health Commissioner of Buffalo. He says there was recently a secret meeting of the health authorities of five of the chief cities on the lakes, generally understood to be Toledo, Chicago, Toronto, Buffalo and Detroit, at Cleveland, when a demand for better smallpox sanitation in Cleveland was made. Cleveland has had this year nearly one thousand cases and Buffalo, in view of her big show, is alarmed. It is suggested that a strict quarantine be demanded at Cleveland and that for

a time no trains be permitted to stop and land or take on passengers there and that the same precautions be arranged with regard to the steamboats. The authorities of Cleveland are said to be very much wrought up over the possibility of a general demand for such action.

Plague Case Near London.—At Willesden, a suburb of London, a man supposed to be suffering from the lightest form of bubonic plague was discovered last week. Persons with whom he had come in contact were detained, but have now been released. The patient himself is now under observation.

Roentgen Society of the United States.—The preliminary announcement of the Roentgen Society has been sent out. The following gentlemen are the present officers: President, Dr. Heber Robarts, of St. Louis, Mo.; First Vice-President, Dr. G. P. Girdwood, of Montreal, Canada; Second Vice-President, Dr. H. P. Bender, of Brooklyn, N. Y.; Secretary, Dr. J. Rudis-Jicinsky, of Cedar Rapids, Iowa. The second regular meeting of the Society will be held in Buffalo, N. Y., September 10-11, 1901.

Plague Spreading in the East.—In spite of the fact that the plague is spreading in the Punjab, where it has already invaded several hundred villages, the repressive measures have so dangerously irritated the natives that the Government has been obliged to order a wholesale relaxation of the plague regulations. Sir Henry A. Blake, Governor of Hong-kong, reports to the Colonial Office that during the week ending May 25th there occurred in Hong-kong 187 deaths from the bubonic plague.

Yellow Fever and the Mosquito.—Dr. Finlay, son of the originator of the mosquito theory of yellow-fever propagation, arrived in this country this week from Havana. Dr. Finlay, speaking of his father's work, is reported to have said: "My father, when he discovered that mosquitoes spread yellow fever, caught one of the pests, and, after starving the insect for two days, allowed it to bite himself. This test, however, was not a good one, as he is an immune, and then the same test was applied to a subject who was susceptible to the disease. The latter contracted the fever in this way, and then hundreds of similar experiments followed, and all the subjects developed yellow fever. Dr. Lazier, one of the Yellow-Fever Commission, who died under the experiment, allowed himself to be bitten by five or six mosquitoes, and in that way got an unusually heavy inoculation. As the experiments proceed, it is believed that in time a virus obtained from either a patient or a *Culex* will be procured, which, when modified, can be used as successfully as is bovine virus for smallpox."

Obituary.—Dr. John E. Comfort, one of the best-known physicians in the Borough of the Bronx, and a member of the New York County Medical Society, died at his residence on May 29th. He was born in St. Louis, Mo., October 6, 1837, graduated at the Albany Medical College in 1864, and entered the United States Army Jan. 19, 1865, as Assistant Surgeon of the Sixtieth New York State Volunteers. For more than thirty years he had a large practice in the upper wards of the city and served twelve years as Inspector on the Board of Health.

Dr. T. A. Bowling, of Hammondsville, Ky., was killed May 29th by an accident.

Dr. John A. Feeny, sanitary superintendent of the borough of Richmond and one of the leading physicians of Staten Island, died May 31st at his home on Beach Street, Stapleton, Staten Island. He had been seriously ill for three weeks with a complication of diseases. Dr. Feeny was born at Stapleton in September, 1845, and was the second son of Dr. Joseph Feeny. He was graduated from the medical department of the University of New York in 1866.

Dr. Seth B. Sprague died at his home in Jersey City, June 5th, from a complication of diseases. He was born at Dexter, Me., Jan. 12, 1840, and was graduated from Bowdoin College. He removed to Jersey City in 1890 and built up a large practice. His eldest son is Dr. Ezra K. Sprague of the United States Marine Hospital Service.

CORRESPONDENCE.

OLLIER MONUMENT FUND.

To the Editor of the MEDICAL NEWS:

Dear Doctor: Some time since you kindly published an appeal of a committee soliciting subscriptions for a monument to the late Prof. Ollier in Lyons. As Treasurer of the Committee, I beg that you will publish this letter in your journal in order to inform the profession that I have received the sum of $649.00 from 103 subscribers. I have forwarded the same, less $4.60 for postage, printing, etc., to Dr. G. Mondan, 27 rue Jarente, Lyons, France.

W. W. KEEN, *Chairman.*

1729 Chestnut St., Philadelphia, June 3, 1901.

OUR LONDON LETTER.

[From Our Own Correspondent.]

LONDON, May 25, 1901.

AN UNEVENTFUL WEEK—ANTIVIVISECTIONISTS IN COUNCIL—THE TWO SECTS OF ANTIVIVISECTIONISM—MR. STEPHEN COLERIDGE AND MISS FRANCES POWER COBBE—THE "ABOLITIONIST"—THE VALUE OF LAWSON TAIT'S TESTIMONY—A STORY OF SIR WILLIAM GULL.

"ALL'S well with the world," as Browning's passing Pippa sings—at any rate, with the medical world here for the moment. The Committee appointed to inquire into the affairs of the

National Hospital for the Paralyzed and Epileptic, where the medical staff and the lay governors are fighting for the crown, appears to be going about its business in a workmanlike manner; the Committee which has taken in hand the reconstruction of the British Medical Association is considering whether anything of a revolutionary character can be done in face of the fact that of a membership of nearly 20,000 scarcely 1,000 have been at the trouble to vote at all; the reformers of the medical service of the army have for the present ceased to trouble; and the organizers of the Tuberculosis Congress have after much bickering and intriguing practically come to an understanding.

The past week, therefore, as far as strictly medical affairs are concerned, has been uneventful. One has, therefore, to go outside the realm of medicine to find matter for a letter. But one has not to go very far afield, for the antivivisectors lie just outside our frontier, and they have been gathering in force and like their friends, the dogs in the hymn, barking and biting as 'tis their nature to. Last week the National Antivivisection Society held its annual meeting, at which the proceedings as usual took the form of a debauch of emotional excitement over the supposed tortures inflicted on animals in biological laboratories. If one may judge from the character of the assembly the antiscientific movement finds no support either in the brain or the heart of the country, for as far as can be gathered it was attended by no one of any intellectual importance or whose name is known in association with philanthropic work. Our antivivisectors are mostly of that curious type of humanity which finds its embodiment in the phrase of a distinguished American writer, in "long-haired men and short-haired women." One has only to see them to recognize the outward and visible signs of the crank. If Lombroso's view is right that there is a close affinity between neurosis and genius, there must be a vast number of latent Shakespeares and Goethes among the antivivisecting fraternity.

There are two main sects among our vivisectors which hate each other with an almost theological intensity. One of these is represented by the National Antivivisection Society aforesaid, the moving spirit of which is Mr. Stephen Coleridge; the other is the British Union for the Abolition of Vivisection, which derives its inspiration from Miss Frances Power Cobbe. Mr. Coleridge is a son of the late Lord Coleridge, Lord Chief Justice of England, in whom the antiscientific bias was very pronounced. Some revelations of his home life which were made in the law courts a good many years ago showed that however kind he may have been to animals, he was not always tender to his own flesh and blood. Edmund Yates (whom he put in prison and who may, therefore, have been a little prejudiced) never referred to him in the London *World* except as the "Roman Father." Neither the present Lord Coleridge, who practises at the bar, nor his brother Stephen, also a lawyer, is particularly popular; they are warm champions of the rights of animals, but their manner does not give the impression of a burning love of their own species. And the virulence with which Mr. Stephen Coleridge denounces all who say a word in defence of vivisection, the subtle misrepresentation with which he seeks to damage all hospitals which have vivisectors on their medical staff, and in particular the rancorous abuse which he loses no opportunity of flinging at that great benefactor of mankind, Lord Lister, would lead one to believe that he holds human suffering and human life cheap compared with even temporary inconvenience to an animal.

Vivisection in this country is already surrounded by so many restrictions that we are falling more and more behind the rest of the world in the matter of research. Licenses of a complex character have to be obtained from the Home Secretary and all laboratories are subject to Government inspection. The antivivisectors say the inspection is a farce and hint that the Home Office is in collusion with the experimenters to conceal the horrors of the physiological torture chamber. But those who are acquainted with the facts know that the inspection is a serious business and that violation by a worker of the terms of his license would lead to its revocation; further, that any act of needless cruelty proved against him would bring him within the clutches of the law.

The antivivisectors, however, will be satisfied with nothing less than the complete abolition of all experimentation on animals. It is on the question of the way to secure this result that they have fallen out among themselves. Mr. Stephen Coleridge is a political tactician and will take what he can get while reserving of doing like Oliver Twist and asking for more, when the time seems ripe for such a demand. Miss Frances Power Cobbe, however, insists on a policy of what Strafford in governing Ireland called "thorough." She will not tamper with the accursed thing, and if she could have her way would doubtless have all vivisectors and their supporters burnt and their ashes scattered to the winds. Miss Cobbe's pen and tongue used to be ceaselessly active in the denunciation of biological research, and her language was like that of the invalid in one of Bret Harte's poems "painful and frequent and free." But some eight or nine years ago Mr. Victor Horsley took the field against her and proved himself a much superior master of vituperation. Thus beaten with her own weapon, Miss Cobbe retired into the shelter of the "silences" of which the world used to hear so much from Carlyle. But unchilled by the winter of advanced age the hatred of vivisection still rages in her breast, and disdaining compromise she insists on its absolute suppression. The British Union for the Abolition of Vivisection of which she is the prophetess has as its mouthpiece a journal entitled the *Abolitionist* which not long ago made the exhilarating discovery that vivisectors torture the animals used for experiment for the same pur-

pose that "Jack the Ripper" mutilated his victims. Vivisection is in fact, according to this charitable theory, a peculiarly revolting form of Sodism.

Among the few medical authorities whom the antivivisectors cite to give evidence in their favor is Lawson Tait. I see he is quoted by their brethren on your side of the water too. It may be well, therefore, to indicate the value that should be attached to his testimony in the matter. Lawson Tait was a daring surgeon and a brilliant operator within his own limited sphere of practice; but he was also a master of the art of *réclame*, and he knew well how to tickle the ears of the groundlings. Very likely his dislike of vivisection was sincere enough, but his conviction of its uselessness was doubtless greatly intensified by the fact that Spencer Wells had said that it was by experiments on animals that he had learned how to perform ovariotomy successfully. It was enough that Spencer Wells should say a thing for Tait to say the opposite. Moreover, to speak plainly, Tait had in him much of the bully and the coward. He was blusterous in assertion, but often strangely backward in proof. At a Church Congress held at Folkestone some years ago, a debate on vivisection figured prominently on the program and Lawson Tait's name was "billed" for an address on the subject. When, however, it was announced that Victor Horsley was to be on the platform, Tait's controversial valor oozed like that of Bob Acres out of his finger ends, and he failed to put in an appearance. It was rather a habit of his to send a bold challenge—to a fight in the lists of the law courts or elsewhere—and when it was taken up by the threatened party, to find it convenient to subside. Lawson Tait had, as already said, his good points, but in regard to experiments on animals the value of his testimony may most politely be expressed in the language of the tailor who said Falstaff must procure him some better assurance than Bardolph; he liked not the security.

In a book recently published by Canon Fleming, a popular preacher in high favor with the Royal family, there is a story about the late Sir William Gull which is characteristic of that most diplomatic of physicians. Gull was with the present King, then Prince of Wales, during the attack of typhoid fever which nearly cut short his career thirty years ago. The Duke of Cambridge went to Sandringham, and was about to ask Sir William about the patient, when the physician began drawing on the back of a telegram. "What are you doing?" asked the Duke. "I am drawing a picture, Sir, and underneath I purpose writing, 'Never speak to the man at the wheel.'" Gull's tact gave him a great advantage over colleagues who knew just as much or more than he did. One of the best instances of this is the way in which he satisfied the inconvenient curiosity of the wife of a well-known financial leader in Israel. The millionaire was suffering from Bright's disease for which he had for some time been attended by the late Sir Richard Quain. It was thought advisable that the anxious wife should not know the exact nature of her husband's disease, and she on her side made the lives of his physicians burdensome to them by her persistent cross-questioning. She suggested that Gull should be called in, but the doctors in possession did not relish the idea of having so powerful an auxiliary forced upon them. At last, however, they could no longer decently resist. Gull came and, as usual, saw and conquered—not the disease but the lady. After he had examined the patient the wife said to the great man that none of the others would tell her what was the matter with her husband, and she pretty plainly hinted that she did not believe they knew. She gave the oracle to understand that she looked to him for an answer. It might have been said of Gull, as it was of Lord Chancellor Thurlow, that no man could ever have been so wise as he looked; and in this critical situation he looked as wise as one of Minerva's owls. "Madam," he solemnly replied, "your husband is suffering from a cachexia!" "There" said the lady "I *knew* Sir William Gull would know." So the services of the other physicians were politely dispensed with and Gull was left master of the field. Quain, who, like the incredulous Scotchman of the legend, was something of a "lear himsel'," used to relate this story as showing Gull's superiority in the art.

DILATATION OF THE ESOPHAGUS—MULTIPLE PERIOSTITIS — DIAPHRAGMATIC HERNIA — PULMONARY SYPHILIS—RADIOSCOPY—GIANT-CELL DEGENERATION OF THE HEMOPOIETIC ORGANS—EPIDEMICS OF CEREBROSPINAL MENINGITIS—HYPERTROPHIC HEPATIC CIRRHOSIS.

STRAUSS, at the Nineteenth Congress for Internal Medicine, Berlin, 1901, showed an esophagus from a twenty-nine-year-old man presenting at the middle and lower thirds a curious idiopathic sacculated dilatation, which measured fifteen centimeters in its smallest and thirty centimeters in its largest dimension. So far as the pathogenesis of this condition is concerned he laid stress upon the important effect of arrest of post-fetal development, especially in the mucosa, and of various early lesions of the mucosa which might contribute to the onset of the enlargement. He then showed several instruments designed to diagnose such dilatations of the lumen of the viscus.

VON JAKSCH exhibited the bones from a case of multiple periostitis observed in a young girl and belonging very probably to the category of blood diseases, perhaps of the myelogenous leucemic type. In a few of the bones, especially the radius, the process healed during the course of the disease. Roentgen-ray photographs showed the generalized periosteal lesions. During the course of the disease the mononuclear neutrophile cells continued to increase in a regular

ratio, while the polynuclear proportionately decreased in number. The eosinophile leucocytes became more numerous just before death. A little later large nucleated red cells began to appear and then later polychromatic degenerated forms. At the autopsy the spleen was found to be enlarged and the bone-marrow in a few bones more or less atrophied.

Struppler presented a young man who for six and a half years had had diaphragmatic hernia, following traumatism. The affection was diagnosticated early, and had on one occasion been mistaken for pyopneumothorax, as is so common in such cases. The author then demonstrated the peculiar physical signs of the patient. Skiagraphs served to substantiate the signs. It was evident that the stomach, great omentum and some of the small intestines had come through the diaphragm into the left thorax and were occupying its central portion. The symptoms were more or less pain and distress on eating.

Hausemann raised the question whether or not it is possible to diagnosticate syphilis of the lungs distinctly as such, as contradistinguished from tuberculosis and its cheesy deposits. Since Virchow first raised the point it has remained an unsettled question. The difficulty comes in when there is nothing characteristic especially about the lesion as seen on the autopsy-table. We have the hepatization. The microscopic appearance may be largely similar, but the absence of the bacilli in the sections and the failure of animal-inoculation will strongly suggest that syphilis is the underlying disease, especially if there are other signs of it in the viscera.

Levy-Dorx discussed the problems of Roentgenoscopic dermography, stating that the error of all radioscopic pictures is that one cannot see just what is the condition and position of the organs at the time of the exposure. If the photographic plate is laid directly upon the skin this difficulty is at least in part overcome. For a long time he has endeavored to reduce this to practical and methodical solution. His early experiments were aimed to determine the depth from the skin in a vertical direction of deeply situated bodies, like the viscera and foreign substances. He finally demonstrated a new apparatus which in both the recumbent and the erect position of the patient permits of accurate estimate of the position of the viscera, such as the heart and diaphragm, by a simple parallel displacement.

Michaelis described a case of giant-cell degeneration throughout the blood-producing organs accompanied by a curious condition of the blood. The patient was a woman fifty years old who had gone through an attack of the grip a few months before, but had never fully regained her strength, because her appearance was always cachectic, although upon admission to the hospital she was not yet emaciated. Upon physical examination, the spleen was found to be very much enlarged, but the lymph-nodes throughout the body appeared to be normal. The blood examination showed a moderate increase in the white blood-cells (1:220), the lymphocytes were very numerous (75:100), the neutrophilic myelocytes were also increased to 7:100, nucleated red cells were found at first but later apparently entirely disappeared. There was at no time any hemorrhagic diathesis. At the autopsy the spleen was found to be extremely soft, the lymph-nodes nowhere were swollen, the bone-marrow was red but not very soft, and the bones themselves were not altered. Microscopically the giant-cells of the bone-marrow were much increased in number and they were found invading the liver and the spleen. In each of these two organs were also found several small-cell infiltrations. Perhaps it was an example of some disease of the bone-marrow with augmentation of the giant-cells which escaped into the blood and invaded the other organs of the body. Certainly the woman had some form of leucemia.

Jaegor spoke of the spread of epidemic cerebrospinal meningitis. While earlier there are no reliable statistics concerning the contagiousness of this disease, the epidemic in the Thirteenth Imperial Wurtemburg Army Corps has furnished a good field for observation. In addition to the bacteriological features of lumbar puncture, which can now be observed in almost all cases, the results of modern statistics must not be forgotten. The results of statistics will be best when the various laws governing contagious diseases are brought into agreement. His own tables prepared from the German records point to rather a good outlook as to the absolute communicability of this disease. In certain parts of the world, especially in the densely populous sections of New York and Massachusetts, the disease in an epidemic type seems to be settled and almost endemic.

Hirschberg spoke of the operative treatment of cirrhosis of the liver which has always been regarded as an incurable disease, especially in the hypertrophic forms. He submitted the history of one case, a man, fifty-one years of age, who had been suffering a long time from an actively progressive cirrhosis so that the liver had hugely increased in size. The theory of the disease which the author holds is that ordinary hypertrophy is not at the expense of the parenchymatous cells of the viscus until later in the disease. The fibrous tissue increase, however, is of such a character that the intravisceral gall-passages and their radicles become more and more obstructed, until finally a real retention of the bile is present with secondary cell-degeneration and jaundice. With such a standpoint for explaining the sequence of lesions and symptoms, it follows that any operation must seek to relieve this retention of the bile. In his patient he exposed the liver and made a long, deep cut in its surface and found that a copious evacuation of the bile took place for five days after the procedure and continued in slowly decreasing quantity for a month. Spontaneous cure of the fistula followed. One year after this treatment the man had gained twenty-five pounds and was in excellent condition.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held at St. Paul, Minn, June 4-7, 1901.

[Special Telegraphic Report.]

GENERAL SESSION.

FIRST DAY—JUNE 4TH.

After the call to order the meeting was opened with prayer by Bishop H. B. Whipple of St. Paul, Minn. An address of welcome by Hon. R. A. Smith, Mayor of St. Paul, gave medical visitors the freedom of the city. The feature of the opening session was a magnificent address by the President, Dr. C. A. L. Reed of Cincinnati. (See page 885.)

Dr. Pennington of Chicago presented the portrait of Dr. N. S. Davis of Chicago one of the founders of the Association and a former president. At his suggestion a committee was appointed to obtain without cost to the Association the portraits of other ex-presidents.

Dr. George H. Simmons, the Secretary of the Association, reported the membership at 10,600, an increase of nearly 1,600 during the year, the largest increase in its history. Dr. L. D. Bulkley of New York reported for the Executive Committee that hereafter the number of papers to be read before Sections would be limited. The resolution proposed by him that the title of no paper would be announced if an abstract of it was not furnished by the writer was adopted.

For the Board of Trustees, Dr. Happel of Tennessee reported that the total receipts of the Treasurer of the Association for the year were $131,787. There remains in the treasury $31,864 and besides $10,000 has been spent for machinery for the *Journal* of the Association. The plant of the *Journal* and money on hand is equal to more than $50,000. So far this year advertisements in the *Journal* have paid an average of $1,000 per week, although a new policy of limiting advertisements strictly to such drugs as are not advertised in public newspapers has been adopted. Dr. Happel moved that the officers of Sections should be made responsible for the publication of papers from their Sections. They should be given power to reject papers deemed unworthy of publication and also to compress papers that are too lengthy. This resolution was adopted unanimously.

H. I. E. Johnson of Washington for the Committee on Legislation reported that the Senate bill on Antivivisection had been effectually killed during the last meeting of Congress and its resurrection now seemed hopeless. He suggested the adoption of a motion as to standing committees in each State to influence members of the Legislature.

SECTION ON PRACTICE OF MEDICINE.

FIRST DAY—JUNE 4TH.

Advances in Medicine.—The session was opened by Dr. Anders of Philadelphia, Chairman of the Section, who delivered the annual address. The advances in medicine in the present century, he said, had come mainly in diagnosis. They had been great and accomplished much good for medicine. Of late years there had been more interest than before displayed in the development of therapeutics. This had in some instances degenerated into a too great leaning towards new remedies. Novelty has often been the only reason for prominence obtained by certain drugs. Of this the profession has reached a realization. Members of the profession who introduce new drugs after only very limited experience with them no longer enjoy the prestige they had. This is as it should be.

Recent Therapeutics.—The most encouraging thing about recent therapeutics is the marked tendency to revert to common-sense methods in the employment of physical and physiological means for the treatment of diseases. Recently renewed interest has been awakened in dietetics and hydrotherapy. Dietetics especially constitutes a most promising field. The more the new century devotes itself to it, the surer will be our absolute progress in the cure of disease. This must after all be the main object of the discussions on practice of medicine, although the tendency of late has been to relegate matters of therapeutics to the special Section on that subject. This is unfortunate and must be remedied by the greater attention of the medical section to practical subjects.

Appendicitis.—Dr. John B. Deaver of Philadelphia said that appendicitis is an eminently proper subject to be discussed before the Medical Section since most frequently appendicitis came first for treatment to the medical practitioner. The appendix is more liable to destructive inflammation because it is an organ now in course of disappearance; it has a small canal in a long structure and it is intimately in contact with large accumulations of microbes in the intestines. The bacillus coli communis, an almost constant inhabitant of the intestinal tract, is especially liable to set up inflammation of the appendix if for any cause it becomes imprisoned in that structure. As soon as a condition develops in any hollow viscus in which evacuation becomes impossible, operation is absolutely indicated. This is true of the bladder, the bowels, the stomach. As soon as this condition is established these cases become surgical in character and pass out of the physician's hands. This is just what occurs in appendicitis in all its forms.

Types of Appendicitis.—The disease may be acute or chronic. Acute appendicitis may be

catarrhal, interstitial, ulcerative or gangrenous. Chronic appendicitis may be catarrhal, interstitial, or, finally, obliterative. It is this last type that has constituted the supposed justification for the medical treatment of appendicitis. It is argued that Nature often obliterates the appendix and so brings about a spontaneous cure in many cases of appendicitis. This argument is founded on an illusion. The cases of obliterative appendicitis are extremely rare. In thousands of cases in his personal experience Dr. Deaver has seen obliteration of the appendix occur only in less than a dozen cases. To wait and hope for this one chance in hundreds is to abuse the patient's confidence and waste precious life-saving opportunities.

Nature's Protective Efforts.—In these cases such are often sadly misdirected. She means well but accomplishes very little. Even when she walls off infective material, it is but temporizing with a deadly enemy. Abscess formation does not ensure the patient from sudden and unexpected peritonitis on very little provocation. When rupture of the abscess into a hollow viscus like the bladder takes place the patient's condition is only temporarily improved and only very slight protection against fatal peritonitis is afforded.

Symptomatology.—In all abdominal affections the first requisite for safe diagnosis is to exclude appendicitis. This is a precious rule for practical life. All colicky pains in the abdomen are to be suspected of connection with the appendix. The pain need not be localized at McBurney's point. Practitioners deceive themselves and incur great risks for their patients by placing any dependence on the belief that pain at McBurney's point is necessarily present in appendicitis. If the type of the appendix is in the pelvis the pain will often be referred to the vesical region and may be distinctly in the median line. In certain of these cases reflexes are sent down along the spermatic plexus of nerves and there may be retraction of the testicle precisely as in stone in the kidney. This makes differential diagnosis extremely difficult. Operation may have to be done on suspicion, but will be justified if there is any localized tenderness.

Abdominal Tenderness.—This is an extremely important symptom. If there is an area in the abdomen tender to the touch it indicates localized inflammatory disturbance. If the tenderness is exquisite and limited to a small area, it means pus formation. This indicates operation. To discover this acute tenderness palpation must be carefully performed beginning at a point well distant from the suspected site of inflammation. To palpate roughly is not only to obscure the condition, but it may do positive harm by rupturing fine adhesions.

No Symptoms Pathognomonic.—Much study had been given to the question of the time to operate. The temperature was said to provide valuable indications, but it is untrustworthy. Pus may develop rapidly in a walled-off space without temperature. The pulse is no surer in its indications. Blood-counts give information, but do not decide the question. In fulminant cases leucocytosis fails to develop. In many cases the leucocytosis will not be pronounced, yet surgical experience shows the operation needed.

Differential Diagnosis.—As to the kidney-stone and gall-stone, the question of differential diagnosis becomes most difficult. In dubious cases, operate. There is much less danger in exploratory operation than in delay. In women extra-uterine pregnancy and ovarian disease are difficult of differentiation, but as they need operation quite as much as appendicitis the surgeon has less disquietude. Typhoid fever in its incipient stages often simulates appendicitis so closely as to make differentiation practically impossible. The hope is in the history of possible exposure and the prevalence of typhoid at the time the symptoms declare themselves.

Cured Cases.—These are illusory. There is always a focus left in which the tissues are less resistant. Subsequent attacks are almost sure to occur. No one, no matter what his experience, can foretell the course of appendicitis or how severe the next attack will be. To permit pus formation without surgical intervention is almost a crime. The ordinary medical treatment for appendicitis is little better than high-grade Christian Science. The interval is an indication for operation. Early operation is life-saving. Much more harm is done by delay than by operation.

Value of Leucocytosis.—Dr. De Lancey Rochester of Buffalo said that when leucocytosis occurs there is surely pus formation. When there is hesitancy as to the necessity for operation, this gives a decisive indication. In a recent case where parents refused to permit operation, the assurance of its absolute need was confidently given after the leucocytosis had been shown to exist. A number of blood-counts were made and always, when the temperature was high, the leucocyte count was also high. The toxins whose absorption caused the fever evidently influenced the number of white cells. Appendicitis may be recovered from even when very severe and may never recur. Every physician has had these cases. In Dr. Rochester's experience a man of thirty-five refused absolutely to be operated on. He recovered after a severe attack with a large easily palpable appendix. Nearly ten years have passed, yet he has had no recurrence.

Appendicitis a Surgical Affection.—Dr. Kelly of Philadelphia said that appendicitis is never a medical affection. In the physician's hands the patient gets well only by happy chance. There is no guarantee against recurrence. Modern progress points to surgery

dominating this field with ultimate benefit to all our patients.

Course of Appendicitis.—Dr. Smyth of Memphis said that no one can foretell the course of an appendicitis. It does not depend on any factors that can be determined beforehand. It is not in the least dependent on medical treatment; in fact, it is not influenced in the slightest by the medical plan of campaign, whether it be the opium that masks the symptoms or the salines that may increase them. The only assurance for the practitioner is an aseptic scalpel.

Appendicitis, Theory and Practice.—In theory Dr. Deaver's advice to operate for every pain in the belly may be a good one, but for a patient to submit to it, he must have the stoical heroism of an old Roman and the faith of a Daniel. We must consider not what is ideally best, but what our patients will accept as for the best. There seems no doubt that many cases of appendicitis will recover under simple medical treatment. This does not mean any special drugs, but absolute rest, absolute abstention from food and the free use of salines, with an ice-bag locally. Under this plan of treatment there seems no reason why most cases of appendicitis do not get well without operation. Even surgeons admit that eighty per cent. of the cases of appendicitis do not need operation. It must be remembered that all scalpels are not aseptic and that many cases are lost as the result, perhaps, of needless operation. The medical man should if possible always have a surgeon in consultation, but must be conservative in agreeing to an operation.

Prophylaxis of Appendicitis.—Dr. Boardman Reed of Philadelphia said that not only is there danger from an operation for appendicitis at the time of its actual performance, but there are often unpleasant complications and unfortunate sequelæ. The duty of the medical man is to prevent the occurrence of acute attacks of appendicitis. Often for a long time before its actual outbreak there are symptoms that point to the gathering storm. There are often months, sometimes years, of impaired health. There is constipation with intervals of diarrhea. There is often persistent and increasing anemia. In the urine there are the signs of disturbed intestinal digestion. Indican may be found, the sulphates are in excess and the acidity is increased. There is often obstinate gastric disturbance and especially increased acidity of the stomach. This gives rise to catarrhal irritation of the intestines which also involves the appendix. If these symptoms are relieved before they terminate in pathological changes the appendicitis may be prevented. This is the problem the medical man must set himself to solve.

Rigidity as a Symptom.—Dr. I. N. Love of New York said that rigidity of the abdominal muscles on the right side is often the first symptom of appendicitis and it is always a most valuable sign. Nature thus splints the intestines and indicates the plan of treatment she wishes followed. Rigidity if looked for may lead to the very early discovery of appendicitis, when often all that is needed is absolute rest in bed and fasting to make the patient as well as ever.

Fulminant Appendicitis.—Dr. Lily of Memphis reported a case of fulminant appendicitis in his own son. The boy, a strong athlete of twenty-one, took luncheon in good health at twelve o'clock, and an hour later was almost in collapse. A hernial tumor developed on the sight side. This subsided while on the way to the hospital. Operation was postponed until the following morning when five inches of the ascending colon were found to be gangrenous and three inches of the large intestine so congested as to require removal; in addition to this five inches of the ileum were gangrenous. In all thirteen inches of intestine were removed and the patient recovered. The case illustrates how serious the condition of the appendix itself and neighboring structures may become within a few hours after the beginning of the attack. No confidence can be placed in seeming remissions. They often mean only that the disease is taking a fresh start.

Change of Opinions.—Dr. Deaver said in closing the discussion that the medical opinion with regard to appendicitis is gradually changing fortunately for the better. Five years ago the present discussion could scarcely have ended so favorably for the surgeon. True conservatism in the case of appendicitis the medical world has come to realize is early surgery; many lives will thus be saved.

Phases of Malaria.—Dr. J. B. McElroy, of Stovall, Miss., described some anomalous types of malaria. Comatose conditions in other countries develop only in malaria of the estivo-autumnal type. In the United States, however, some few cases of real malaria coma develop from the spring tertian and quartan types of malaria. The perniciousness of malaria is a feature of the estivo-autumnal type, because the parasite of this form of the disease develops very abundantly and affects many red cells. Their destruction leads to clogging of the capillaries and consequent disturbance of all function.

Malarial Gangrene.—A certain number of cases have been reported in which gangrene of the extremities occurs. These cases are sometimes symmetrical, so that there is question of Raynaud's disease. Osler has reported some of these types. In one patient reported by Dr. McElroy, gangrenous spots occurred over the knee-cap and the anterior tibial surface. The patient in his delirium left his bed to sit near the fire, but he had not touched the fire itself. In another patient, a child, the foot and leg became cold below the knee and

then dry gangrene set in. The line of demarcation began to form. During two weeks the patient was not seen and spontaneous amputation had taken place.

Malarial Hemoglobinuria.—Hemoglobinuria occurring in the course of malaria is practically always in Dr. McElroy's experience due to the malarial intoxication. The British Royal Commission of Invesitagtion found 90 per cent. of black-water fever to be malarial in origin. In these cases the malarial parasites are not found in the peripheral circulation. Dr. McElroy found them in only two out of nine cases. There is no true leucocytosis in malaria. There is sometimes an apparent increase of white cells, but it is that the large mononuclear leucocytes are increased at the expense of the other forms. In malarial hemoglobinuria this is the form of leucocytosis that occurs. This confirms the suspicion of its malarial origin.

Negro Immunity to Malaria.—Dr. McElroy thinks there is no foundation for the tradition that negroes are comparatively immune to malaria. In the whites on a plantation in Dr. McElroy's neighborhood about 53 per cent. are malarial, among the blacks over 60 per cent. The negro mortality from the disease is over 30 per cent., that of the whites under 25 per cent.

Negroes Relatively Immune.—Dr. Wm. Britt Burns in the discussion said that the blacks are relatively immune. They take the disease, though much more exposed than the whites, in milder form. They respond better to treatment. Whites practically never recover from malarial coma. It is not rare to see a negro recover. Children of the whites are in serious danger if they have more than three chills. Black children stand many and yet remain comparatively strong in spite of the most unhygienic surroundings.

Section on Surgery and Anatomy.

First Day—June 4th.

Medical Treatment of Appendicitis.—Dr. A. J. Ochsner of Chicago dwelt chiefly with the new and what might be called quasi-medical treatment of appendicitis. Its exhibition deals chiefly with the prevention of diffuse general peritonitis which is so often a fatal accompaniment of this disease. Except toward the median line, where the small gut alone safeguards the appendix, very efficient protection is afforded this organ in all directions. The omentum, which normally and invariably in pathological conditions spreads its protecting mantle well over the appendix, affords not only a certain amount of mechanical protection and support, but by its vast blood-supply aids materially in draining away and destroying the exciting factors of the inflammation Rest is here as emphatically indicated as in inflamed areas elsewhere. The tense board-like abdominal walls the spasticity of the body on the affected side; the absence of peristalsis, all point tentatively to this great truth. Consequently it seems but rational that any treatment which can be inaugurated to give help and support to these splints of Nature or which, at least, shall in no way interfere with them, must be a rational and a safe one. It is summed up simply as follows: (1) No particle of food shall pass the mouth after the inception of the disease; (2) under no conditions shall cathartics of any character be administered; (3) gastric lavage repeated as often as may be necessary to abrogate meteorism and pain shall be freely used. No matter what may be the form of the disease, this treatment seems invariably beneficial, but more particularly in the fulminating and gangrenous forms in cases which have been aptly described as too late for early operation and too early for late, are the beneficent effects of this treatment manifested. Ninety per cent. of these cases are converted into the chronic type, practically all of which terminate in recovery. Of five hundred and sixty-five cases operated in the last four years, Dr. Ochsner is able to show the flatteringly low percentage of 3½ per cent. mortality. This, too, in a series of cases embracing every possible form of appendicitis. He drew the following conclusions: (1) The peristaltic movements of the small gut are the chief factors in distributing appendicular infections; (2) rectal enemata of any predigested food, not more than four ounces, should be given every four hours: (3) this treatment, if instituted at the onset of symptoms, will convert every fulminating case into one of a chronic form. (4) the laity should be instructed to cease giving food and salts in all cases of intra-abdominal distress.

Surgery of the Spinal Cord.—Dr. Andrew J. McCosh of New York said that the general trend of modern surgery gave more and more support to the prophetic sayings of Sir Astley Cooper, to wit: That in all cases where the worst was to be looked for in the event of pursuing a palliative course, the chances of an operation were emphatically indicated. In the light of our modern surgical technic there is no type of operation which more strongly emphasizes the truth of this saying. Operation should be undertaken the very moment a diagnosis is made and in every case where a diagnosis is impossible exploratory incision is called for. Unhappily, as yet the results obtained in surgical treatment of fractured vertebræ are in no way comparable to the brilliant productions of cerebral surgery. Although physiologists maintain that a re-establishment of function after severance of the cord is impossible, Dr. McCosh believes that there is yet ground to hope that under certain conditions this happy termination may be looked for. It is much to be deplored that a

custom has sprung into being which classes all cases presenting symptoms of the tumor of the cord as syphilitic. Despite plausible histories to the contrary, these unfortunates are put on prolonged antisyphilitic treatment, which is usually continued until pressure necrosis has hopelessly disintegrated the cord. There are two types of operative technic. In the first, three spinous processes and their laminæ are divulsed with the rongeur. In the second, a corresponding amount of bony tissue is raised by the flap-method, to be subsequently replaced. This possesses but little merit, is occasionally unhappy in its results and is difficult of execution. The skin incision should be made as high as the lesion will permit in order that trophic changes over the injured cord may be avoided. He feels that particularly in cases of tumor early operation is indicated, that the greater the speed of operating, the better, and that at least three processes should be removed. Spinal supports he considers unnecessary.

Spina Bifida.—Dr. Paul F. Eve of Nashville dwelt on the characteristics of the tumor which not only permit the establishment of positive diagnosis, but which enable one with reasonable security to establish a correct prognosis. Some of these are translucency, elasticity and reducibility, with bulging of the fontanelles. Of particular import is the character of the pedicle. Because of the fatality surrounding this class of congenital malformation, it seems axiomatic that almost any radical measure presents even a shade of hope of complete restoration is justifiable. The day has passed for pressure and for the varied forms of astringent injection. Save in those cases where the breadth and delicacy of the pedical contraindicate, operation of a plastic type seems surely advisable. Particularly is this true where the tumor is increasing rapidly in size and the age of the patient has passed the third month.

Methodical Exploration of the Brain for Fluid.—Dr. Christian Fenger of Chicago spoke only of subcortical collections of pus. The three factors chiefly to be considered in this exploration are the type of instrument to be used, the position of the trephine areas and the extent and direction of the exploration. He gives preference to a blunt aspirating needle, although Von Bergmann advises the simple use of a knife which shall penetrate not more than three to four centimeters. In order most thoroughly to search for the offending material, he takes two trephine areas over each hemisphere, one anterior, the other well posterior. In each of these he passes the aspirator in every direction, and invariably taps the lateral ventricles. He thus fearlessly penetrates from three to four inches of brain tissue. It cannot be doubted that this method is infinitely preferable to the limited procedure of Von Bergmann.

Immediate and Remote Effects of Brain Injury.—Dr. T. S. Fairchild of Clinton, Iowa, believes that a knowledge of the mode of the reception of the injury is of paramount importance. Patients whose brains have been violently contused by their falling from height present conditions very different from those who have been struck upon the head by a concentrated force. Symptomatically he divides these cases as follows: (1) Indeterminate trauma without symptoms; (2) indeterminate trauma with symptoms; (3) determinable trauma with marked symptoms. Anatomically he divides the cases as follows: (1) Those presenting pressure lesions which give rise to Jacksonian epilepsy; (2) nutritional lesions which, leading to minute sclerosis, often ultimately terminate in insanity. The early surgical treatment gives good results and obviates the possibility of these sequelæ; (3) sclerotic cerebral areas often undergo cystoid degeneration.

Drainage of Ventricle.—Dr. W. W. Keen of Philadelphia agreed most cordially with the radical views which had been expressed touching the treatment of spina bifida. He regretted that Dr. Fenger had limited his paper to a description of his mode of searching for pus. Probably more frequent and surely more often diagnosed, the localization of hemorrrhage seemed to him of equal importance. More than ten years ago, in a paper read before the International Congress, he described a method for reaching the lateral ventricles and traced the paths by which they could best be washed out and drained. He further showed that the opening of these ventricles was not dangerous. He recently operated upon a patient whose skull had been fractured in 1892 and who had developed epilepsy in 1899. Immediately beneath the dura he discovered what appeared to be a large cyst. In the absence of cortical covering he did not even think of the lateral ventricles, and he was both astonished and alarmed to find himself suddenly within their cavity. After removing a grumous material the cavity was drained and the patient recovered with a cessation of his epileptic attacks. In epidural hemorrhages it must not be forgotten that the duration of the period of consciousness which characterizes this lesion may vary from nothing to six weeks.

Dr. McLean of Detroit agreed with Dr. McCosh that spinal supports are useless and he felt that in cases of spina bifida considerable care should be exercised before determining upon operation. The cerebral injuries without doubt present two widely separated types, dependent on whether the patient falls or is struck. The first class is by far the most dangerous type since the whole brain is undoubtedly injured, and the patient should be under careful scrutiny for at least two weeks.

Operative Treatment of Tic Douloureux.—

Dr. Frazier of Philadelphia presented the details of new operation for the relief of tic douloureux. In essence it consists simply in a severance of the sensory ganglion, commending itself chiefly for its simplicity, its freedom from hemorrhage and the preservation of the integrity of the cavernous sinus and of the sixth nerve. It calls for a slitting of the zygomatic process.

Dr. R. F. Wier of New York said that surgeons should reach some definite conclusion as to the treatment of cerebral symtoms which do not present classic symptoms. In earlier years he had been in the habit of leaving these cases alone, but observation of the varied accidents which befell them subsequently has led him to believe that the careful exploration of the wound is the conservative surgical procedure. He supports the original operation on the Gasserian ganglion, feeling that the modern paths of approach are in no way superior to the older, and the splitting of the zygomatic arch is certainly an undesirable procedure.

Dr. Earles of Milwaukee declared that, in its close application to abdominal work, surgery had neglected to a lamentable degree the diagnosis and treatment of cerebral injuries. Every trauma capable of fracturing the skull must be capable of injuring the brain. The only safe attitude for the surgeon of to-day is to premise his work with the assurance that there are cerebral injuries and operate accordingly. In 87 per cent. of a large number of cases he has found some form of intracranial lesion.

Dr. Moore of Minneapolis spoke of the indications for operation and the treatment and prognosis of spina bifida. If there be an abundant integument and a narrow pedicle, the prognosis, no matter what the age may be, is usually good. The position of the child is important. It is a sort of reversed Trendelenburg posture. This preserves an equable intracranial pressure no matter at what speed the tumor be evacuated. The chief difficulty seems to have lain in the obliteration of dead space. This he partially accomplishes through the organization of the blood-clot and partly by a free liberation of the erector spinæ muscles from the bone and their close union in the median line.

Dr. Dawbarn of New York cited an anomalous case upon which he had operated for the relief of cortical hemorrhage some years ago. It was done in accordance with the advice and under the eye of the late Dr. L. C. Gray. In the presence of every classic symptom no hemorrhage was found on the operated side. At the autopsy a week later, an immense epidural blood-clot was discovered on the paralyzed side. Dissection revealed the fact that in this case the fibers had not decussated. Although but three similar cases are recorded, he feels sure that it is not a very infrequent anomaly, our unfortunate inability to procure autopsies having limited our information as to these details.

Dr. McCosh in closing emphasized the importance of early operation in all cases, even including those which gave all the apparent symptoms of a complete severance of the cord.

Dr. Fenger in closing said that the lateral ventricles should always be tapped for diagnostic purposes. He uses a half-inch trephine and feels that the grooved director so cordially indorsed by some surgeons for the exploration of the brain is in no way comparable in efficacy to the long blunt aspirating needle.

General Session.

Second Day—June 5th.

Address of Governor S. S. Van Sant, who welcomed the American Medical Association to the State of Minnesota. The freedom of the city had been granted by the mayor. He was pleased to extend to the visiting members the freedom of the State. He spoke with pride of the advantages of the State and after welcoming with special warmth the members from the South, he advocated the Southern territory as a fitting meeting-place for the association in the year of 1902.

Executive Business.—The minutes were read and approved and the report of the joint meeting of the General Executive Committee and the Committee on Re-organization, bearing on the report of this latter Committee, was read by Dr. H. O. Walker of Detroit. Dr. E. Harris moved the adoption of the report *in toto* and, after a short discussion by Drs. Bulkley, McCormack and others, the report of the committee on re-organization was carried and the new constitution and by-laws drawn up by that body now becomes effective for the association.

Oration on Surgery.—Dr. J. A. Wyeth of New York then delivered the Oration on Surgery (see MEDICAL NEWS, page 891).

Senn Medical Prize.—Dr. F. H. Wiggin of New York, on behalf of the Committee of Award of the Senn Medal, reported that two papers only had been received, and as neither of these was deemed worthy of the prize, it was decided not to award it this year.

Scientific Research.—Dr. W. H. Welch of Baltimore, on behalf of Dr. H. C. Wood of Philadelphia, reported to the Association that during the year little advance had been made in the work of this Committee owing to the illness of its Chairman. No money had been expended, although ten applications had been received. He advocated the reaffirmation of the grant, its increase to $1,000 and an increase above the $100 allowed to an individual worker. In this manner it was thought that the better carrying out of the original desires of the founders of the grant would result.

Army Canteen Question.—Dr. Seamans of

New York desired the Association to take some action on this question. After much discussion the matter was referred to the Committee on Legislation.

Rush Monument Fund.—Dr. H. D. Holton of Brattleboro, Vt., reported an addition of about $1,880 to the Fund during the current year. This, with the promise of the Pennsylvania Medical Society of $2,000 when the Fund actually reaches the desired amount, gives a total of $13,941.00 in the Treasury.

Officers.—The following officers were elected: President, John H. Wyeth, of New York; First Vice-President, Alonzo Garcelon of Maine; Second Vice-President, A. J. Stone of St. Paul; Secretary, George H. Simmons of Chicago; Treasurer, Henry D. Newman of Chicago; Trustees, Drs. Fulton, Grant and Happell.

Saratoga was chosen as the next place of meeting.

SECTION ON MEDICINE.

SECOND DAY—JUNE 5TH.

Blood Chemistry.—Dr. W. D. Kelly of St. Paul read a paper on the chemical microscopical value of blood examinations. He detailed the recent chemical investigations of the blood and recalled the salts in solution in the plasma. One noteworthy recent discovery is that of a diastase in the blood. This would coagulate the serum of the blood, but is inhibited by the nuclein present. There is under special circumstances free fat in some form, stearin, olein, or palmitin present in the blood. In fevers acetin can always be found and sometimes in readily recognizable quantities.

Acidemia.—Dr. Kelly has succeeded in injecting large quantities of glacial acetic acid, as much as 1 c.c. into rabbits without causing death. In these cases the blood gives the same test as in the supposed acid coma of diabetes, yet the animal is but very little affected in its general condition. It seems probable, then, that it is not the more or less coincidental presence of excess of acid in the blood that causes diabetic coma, but some other substance present with the acid. Large quantities of alkali may also be injected into the animal circulation without causing death, though materially altering the blood reaction.

New Method of Blood Preparation.—Dr. Kelly then described his apparatus for fixing blood specimens. It consists of a copper box that fits over an ordinary incandescent lamp. This supplies a very constant source of gentle heat and does away with the necessity of having elaborate apparatus for fixing blood specimens, yet absolutely assure their permanence. Dr. Kelly prefers to take specimens for blood examination in the early morning before the patient has eaten, so as to have the circulating blood as nearly as possible in its normal equilibrium.

Pernicious Anemia.—Dr. Thomas MacCrae of Baltimore gave some details of forty cases of pernicious anemia which have occurred during these last twelve years in Professor Osler's service at Johns Hopkins Hospital. These cases serve to throw light on certain disputed points in this important disease. These forty cases occurred among 12,500 medical cases, which serves to show the rarity of the disease. There were 32 males and 8 females. Usually male patients preponderate in pernicious anemia statistics, but the reason for this disproportion is not clear. Two of the cases were in the colored race. The negro is said to be spared by this disease, but Dr. Osler's observation show they are not. The race, however, is relatively immune. While the proportion of black to white patients was 1 to 8 the proportion of those attacked by pernicious anemia was 1 to 20. This confirms what has been found with regard to traditions of negro immunity in other diseases. There is a comparative lack of liability to many diseases, but this does not rise to positive immunity. The more careful the investigation the more cases of special disease found among the negroes.

Age and Other Factors.—Most of the patients were in the fifth decade of life, more than one-half were over forty. In only 3 cases was mental worry or emotional strain mentioned as a positive causative factor. These are considered important elements in causation in private practice, but are not often referred to by hospital patients. In only one of the 8 affected females was there any question of the association of pregnancy or lactation in the causation of the disease. This is all the more surprising as these states are said especially to predispose females to blood disturbances of various kinds and above all to pernicious anemia.

Oral Sepsis.—Hunter's recent statement that septic conditions in the mouth were often causative of the disease led to a careful study of mouth conditions that might be provocative of serious trouble. In 6 patients healthy mouths were found. This investigation led to the examination of the mouths of all patients coming to the hospital. The proportion in which oral sepsis of greater or less degree existed was very high. It was not as high in pernicious anemia as in many other pathological conditions to which, however, it evidently bore no causative relation. Dr. Hunter's discovery of oral sepsis in so many cases is not surprising. It is, however, only a coincidence, for oral sepsis is so common among hospital patients as to be almost the normal condition. Only some special circumstances will have prevented its occurrence.

Gastro-intestinal Disturbance.—A fact that confirms this conclusion contrary to Dr. Hunter's claim is the rarity with which gastro-intestinal disturbance is associated with pernicious anemia. In less than one-third of Professor Osler's cases

were gastro-intestinal symptoms noticeable. It is manifest that it is not the infection of the stomach from the mouth that is at the bottom of the condition.

Symptoms Most Prominent.—The first complaint as a rule is the progressive and unaccountable weakness. This is always an important preliminary feature of the disease the development of the characteristic lemon-yellow color often calls attention to the disease. It seldom fails to make its appearance. Loss of weight is a striking and very common symptom that is usually not found insisted on in the text-books of medicine. In more than one-half of the Johns Hopkins cases this was noted early in the course of the disease. About one-quarter of the patients retain their plump appearance, though being very weak. Hemorrhages from mucous membranes, which are often said to be a characteristic symptom, were seen in 10 cases while under observation. Abdominal examination showed that the liver was practically never enlarged. In 6 the spleen was somewhat enlarged, but not to any serious extent, except in 3 anomalous cases that seem to deserve classification by themselves under the term splenic anemia. They were reported as such by Prof. Osler three years ago. In three-fourths of the patients rises in temperature were noted. Ten cases of pernicious anemia ran their course and were discharged better without having had any fever. As a rule, 101 F. was the average highest daily temperature. Occasional rises to 104° F. were seen however and once even a rise to 106° F. No other cause for the temperature disturbance could be found in any of the cases except the blood condition.

Hemoglobin Average.—In the 40 cases this was exactly 30 per cent. The average blood-count was just one and one-half millions. The disturbance of the ratio between hemoglobin reduction and corpuscle reduction was not found. A reduction in the number of mononuclear leucocytes was not found to be so serious a prognostic sign. Many of the cases in which this occurred were discharged cured. The presence of megaloblasts is of serious prognostic import. The reduction of the red blood-cell count below one million is cause for a bad prognosis. Of 16 cases in which such a reduction was noted only 4 lived to be discharged from the hospital. As to pathognomonic signs in the blood there are none though the presence of megaloblasts is the surest single sign of the existence of pernicious anemia.

Differential Diagnosis.—The most important affection requiring careful differentiation is cancer of the stomach. Usually in this the red blood-count is not below one and one-half millions, though occasionally it is in very advanced stages in pernicious anemia at the time it comes to the hospital the red blood-cell count is seldom above one and one-half million and may be below a million. Rarely is there any improvement in the blood condition of cancer. Rarely does some improvement at least temporarily fail to occur in pernicious anemia.

Leucocytosis after Hemorrhage.—Dr. Geo. D. Head of Minneapolis said that a number of investigators have found that after hemorrhage in man there is a distinct leucocytosis. This is surprising as, of course, white cells are lost during the hemorrhage as well as red cells. Dr. Head's experiments seem to afford a rational explanation of the paradox. In animals artificial hemorrhage is followed first by lowering of the number of white blood-cells, leucopenia, and then some hours later by leucocytosis. This same state of affairs probably obtains after hemorrhage in the human being. There is a preliminary fall in the number of leucocytes followed by the hemorrhagic leucocytosis noted by so many observers. In the discussion Dr. MacCrae of Baltimore said that after hemorrhage in typhoid fever where the case was suspected and blood-counts were being made every hour, he has seen this primary leucopenia and its presence may be a valuable diagnostic sign to differentiate hemorrhage from perforation.

Osmotic Pressure.—Dr. Heinrich Stern of New York said that too much stress has been laid on the physiologico-chemical factors in the production of uremia. This has excluded the physical factors and especially the import of osmotic tension. The intravenous injection of urea and even of the whole urine has not given rise to the symptoms of uremia, as was anticipated. The lacking etiological factor is the disturbance osmotic pressure by the retention in the blood of substances that should be eliminated. There is no new chemical substance in the blood of two uremia patients only an excess of certain substances normally existent there. All organic matter is saturated with water. The cells of the body are more or less permeable for water. If the contents of the organism in soluble salts and in water remain unaltered, so that for a certain period neither salts nor water are introduced nor eliminated, all the watery constituents of the organism would become one homogeneous liquid and the same osmotic pressure would prevail over the entire system. The molecules of a number of compounds when dissolved are divided up and are dissociated into ions. The higher the dilution, the more perfect the dissociation as a general rule. There is no vital process in which diffusion or osmosis does not participate. Conditions for the evolvement of osmotic pressure always exist in the organism, for whenever two solutions come in contact by means of a semipermeable wall, osmotic tension is displayed. When the excretory activity of the kidney is materially interfered with, the products of metabolism are retained in the blood. There are a great variety of substances dissolved in the blood-plasma, each with its special effect on osmotic tension. All of these have a tendency to diffuse toward the less concentrated body liquids. Ultimately all the fluids of the body exhibit a similar degree of concentration. This degree of

concentration is accompanied by a series of manifestations, coördinate and determinate, which have been grouped together under the name of "uremia." This is really, if we may call it so, a mechanical intoxication not one of chemical origin, but one due to an abnormal increase in osmotic tension of the blood-plasma and the fluids of the body. According to Dr. Stern's experiments the phenomena which occur in the blood after the injection of large amounts of concentrated salt solutions are the same as those in uremia. They make their appearance together with the increase in the concentration of the blood, when the elimination of the accumulated substances from the blood on account of the exhaustion of the resorptive qualities of the tissues does not occur any longer. Novy already noticed in dogs tonic and clonic convulsions after intravenous injection of a ten-per-cent. sodium-chloride solution in such amounts that the blood had attained twice its former concentration.

Biological *vs.* Physical Factors.—In discussing Dr. Stern's paper Dr. Walsh of New York said that Dr. Stern has done a service by calling attention to the physical factors that may enter into the causation of symptoms of uremia. To limit the etiology of the symptoms to physical factors alone is to take a very one-sided view of a complex problem. Osmosis and osmotic tension were some years ago advanced by physiologists as an all-sufficient explanation for many vital phenomena. We have gotten beyond the idea, however, that cellular membranes are the active elements in vital activity. The separate cells in their life processes accomplish much more than can be explained on the principal of osmosis. Now that we have advanced a step to the application of the principle of osmotic tension to the individual cells, the influence of this extraneous process must not be exaggerated. Intracellular life is the essential active element in all body changes and the metabolism of the cell remains almost as much a mystery as ever before.

Circulatory Disturbance and Liver Cirrhosis.—Dr. Stockton of Buffalo read a paper on this subject with special reference to the inosculation of the branches of the portal system with the general systemic venous circulation. He said that the most important thing in true atrophic cirrhosis is the circulatory disturbance with congestion of abdominal organs, ascites, etc. There are always some inosculations of portal systemic circulations. Blood does not flow from portal to systemic veins, because blood-pressure in the portal vein is lower than in systemic venous circulation. When, because of the increase of blood-pressure in the liver, due to the atrophic shrinkage, the portal circulation is forced into the systemic, various toxic conditions are produced. These often cause headache, general malaise and discomfort and are best relieved by a saline cathartic. Friederichshalle water seems best suited for this purpose.

Cirrhosis Without Ascites.—In many of these cases the reason for the failure of the ascites to occur is that the portal circulation relieves itself by anastomosing freely with the systemic venous apparatus. This produces enlargement of the veins, especially of the esophagus. These veins may rupture after enlargement and so give rise to fatal hemorrhage. When the atrophic cirrhosis is suspected and no ascites has developed, it is well to be wary of the possibility of the occurrence of serious hemorrhage. In one instance where Dr. Stockton was able to follow the case from the beginning, he foretold the possibility of death from esophageal bleeding and this actually took place. In all cases where the ascites is small in amount or absent, the portal circulation has found some vent for its blood and serious disturbance may be expected. A series of cases was detailed, most of them with autopsy, in which death took place from hemorrhage in what looked like an especially benign form of cirrhosis of the liver.

Cirrhosis from Metallic Poisons.—Dr. Victor C. Vaughan of Ann Arbor, Mich, said that all cirrhosis of the liver is due to the presence of a toxin brought to the liver. The cirrhosis develops in different ways according to the avenue by which the toxic material gains an entrance. If it comes through the arteries, then the sclerosis starts from the coats of the vessels and extends into the liver substance. This is the arteriosclerosis of the liver described by the Germans and accompanied by the like changes in arteries in other parts of the body. If the poisonous material comes to the liver from the digestive tract, then the growth of connective tissue begins around the portal vein and gradually extends. Alcoholic cirrhosis is the most familiar example of this type. If the bile contains the irritating matter, then the cirrhosis takes the form of the biliary or hypertrophic cirrhosis.

Lead and Copper Cirrhosis.—Dr. Vaughan has seen these mainly in house-painters. They neglect to wash their hands before eating and so they swallow no inconsiderable amounts of the metal which accumulates and produces symptoms of poisoning. Lead poisoning also occurs among the attendants on smelters who breathe in the fumes of the metal usually mingled with arsenic. Cirrhosis that develops thus run a clinical course and, unlike that of alcoholic cirrhosis, needs about the same line of treatment. The first and most important consideration, as in the case of the alcoholic patient, is to remove the sufferer from all contact with the toxic material to which he owes his developing condition. The effect of the soluble salts of the metal aluminum upon the liver especially, as seen in baking-powder, is an important question for public health. Dr. Vaughan has found that in animals the soluble salts of aluminum in ordinary alum produce the fatty changes in liver-cells which are so characteristic of cirrhosis of the liver in man.

Treatment of Cirrhosis.—Dr. John H. Musser of Philadelphia said that while cirrhosis of the liver is hopeless as regards ulti-

mate cure, much can be done to alleviate the symptoms. The general condition of the patient must be maintained at a high degree of vital resistance. Bland unirritating food must be given, free catharsis must be employed and the skin must be kept up to the level of its highest efficiency for eliminative purposes. Surgeons are too ready to operate upon cases of hemorrhoids without consulting the condition of the liver. Where cirrhosis exists operation must not be permitted. As the result of the absence of the liver function, the resistive vitality of the organism against infection is much lowered. The grave processes that begin in the rectum at such times are prone to be long and obstinate to treat. Dr. Musser has seen three cases in which such inadvisible operations have been followed by death. Because of the liability to piles the stool should be kept constantly soft and constipation avoided as far as possible.

Treatment of Ascites.—Dr. Musser has found calomel, gr. $^1/_{40}$ every three hours, almost invaluable for its diuretic action. Niemeyer's pill is also deservedly a favorite prescription. As a diuretic apocynum cannabinum is of great assistance in obstinate cases. Most cases of ascites will prove obstinate to drug treatment. Tapping is the only recourse, and this should be performed early and often. Where tapping has to be repeated frequently, permanent drainage is advisable. Tapping is of itself curative. It does not affect the cirrhosis, but it alters conditions in the abdomen so that accumulation of fluid no longer takes place. In one reported case tapping was performed 190 times. The maintenance of permanent drainage involves no risk. By permanent is meant drainage which is continued until the ascitic condition is relieved.

Anastomosis Operation.—In certain cases the symptoms can be relieved by producing anastomosis between the vessels of the abdomen and those of the omentum. In reported cases this has benefited the patient so much as to constitute a practical cure. The peritoneum is scarified and the omentum is fastened to it; adhesions then form in which anastomotic blood-vessels are not rare. The cirrhotic cachexia disapears in many cases as if by magic. Recurrences of symptoms have so far not been noted in the operative cases. Over 20 satisfactory operations have been reported. Even where success is not marked the operation does no harm and is not of itself dangerous.

Biliary Cirrhotic Fever.—In a case of biliary hypertrophic cirrhosis the patient began to suffer from recurrent daily chills and fever. No malaria was present and quinine did not benefit the case. The fever was so exhausted that the end seemed not far off. Laparotomy was done and the gall-bladder incised, careful cultures were made of the bile, but it proved to be sterile. This part of the work was done by Dr. Simon Flexner. A permanent biliary fistula was made and this did away with the chills and fever. This operation of biliary fistula seems sure to acquire vogue in these cases. Undoubtedly in this case it proved life-saving.

Latent Cirrhosis.—Dr. Frank Billings of Chicago said that in some cases the insidious preliminary symptoms of cirrhosis may be detected. Often there is intestinal disturbance with general symptoms, at times localized to groups of nerves. Lumbago-like pains and sciatic neuralgia may be due to defective function of the liver. Under hygienic régimen with special attention to the liver these will disappear. Muriate of ammonia is sometimes an effective drug in the conditions; calomel is always useful.

Biliousness in Incipient Cirrhosis.—Dr. Herrick of Chicago said that the vague group of symptoms, lassitude, headache, tenderness over liver, with constipation and distaste for food, is connected by tradition with the liver. Oftener than is thought these symptoms actually constitute the preliminary signs of developing hepatic cirrhosis. Where they occur frequently their treatment should be undertaken with this view. Calomel should be used at intervals in these cases and chloride of ammonium will be found of good service. Besides atrophic and hypertrophic forms of cirrhosis Dr. Herrick considers there is a mixed form of the affection.

Bronze Diabetes.—Dr. T. B. Futcher of Baltimore reviewed the four cases of this disease that have been reported in this country. The disease is rapidly fatal. Practically it never lasts more than one year. Thirty cases, all in males, have been reported. Nearly always there was an alcoholic history. All the patients were over thirty years of age usually in the fourth or fifth decade. Seventeen of the 30 cases occurred in France. It has been said to be more common there, but it seems that the disease has been looked for more carefully there than elsewhere. It is sometimes mistaken for biliary cirrhosis of the liver. There is always overgrowth of connective tissue in the liver. In 22 cases some connective tissue changes in the pancreas were noted. Gross changes with pigmentation of epithelial cells of the gland were found. This is thought to account for the occurrence of diabetes in the cases. On the other hand, Charcot considered the diabetes primary.

Hemachromatosis. — Dr. Recklinghausen showed that there was a condition in which iron in two forms was deposited in the tissue. Bronzing also took place in this disease, and lesions of the liver were common. In one of Von Recklinghausen's cases diabetes developed before the end. This disease, hemachromatosis, seems to be an early stage of the French bronze diabetes. The same pathological lesions occur in both. Only very recently

has the notion of the identity of these diseases been generally accepted.

Bronze Diabetes and Addison's Disease.—Dr. Futcher in closing the discussion said that it is necessary to take care not to mistake bronze diabetes for Addison's disease. Without examination of the urine the mistake is easily made. In the early stages of hemachromatosis the differentiation may be extremely difficult. The operation of producing anastomosis in hepatic cirrhosis has always done good and at Johns Hopkins is considered a very valuable therapeutic advance.

Rheumatic Simulants.—Dr. James J. Walsh of New York said that acute rheumatism is well known, but that the series of cases diagnosed as rheumatic and supposedly due to chronic rheumatism is a heterogeneous collection of cases of most varied etiology. Relaxation of the tissues around joints, as in flatfoot, is the basis of many of these cases. Old sprains, dislocations, and breaks in the neighborhood of joints, give rise for years after their occurrence, especially in older people, to a series of painful symptoms. In damp weather these are always worse; hence the diagnosis rheumatism and the treatment by antirheumatic remedies. Most of the so-called antirheumatics are really depressants and often irritate the stomach and kidneys thus interfering with nutrition and elimination. This emphasizes instead of ameliorating the condition which goes on from bad to worse.

Toxemic Joint Symptoms.—Joints often become painful in connection with urticaria from digestive disturbance. Arthritic symptoms are common after the administration of diphtheria antitoxin. Ordinary rheumatism of the acute variety is surely microbic, but the presence of bacteria is not necessary for the production of joint symptoms. The tired feeling that accompanies indigestion is often a symptom of the effect of the non-elaborated food substances absorbed into the circulation and affecting first the sensitive mechanism of the joints. The joint structures themselves are more easily affected than other tissues which do not have to work so hard or are not exposed. The occurrence of painful joints should be the signal for careful examination of the patient and the removal of all constitutional disturbances.

Occupation Neuroses.—A prominent group of joint pains are associated with these neuroses. Not alone the penman, telegrapher, violinist or typewriter, may be affected, but any person engaged in an occupation requiring the constant use of a definite group of muscles. Even sweeping, for instance, or ironing or filing may produce at first painful and then crampy conditions. These always develop on a neurotic basis and usually in run-down subjects. The pain is often referred to neighboring joints. It is wonderful how often these cases are discussed as chronic rheumatism. If treated by the salicylates the pains are lessened for the time being, but the condition gradually gets worse. Often these neuroses become noticeable only after the patients have become run-down in health. As a rule, a gain in weight is followed by improvement. Then the patients should be instructed how to use their muscles to the best mechanical advantage and should be warned of bad habits that invite muscular spastic conditions and pain.

Rheumatism and Flatfoot.—Dr. Stockton of Buffalo said in the discussion that the allusion to flatfoot and its being taken for rheumatism is a very practical point. Dr. Stockton has seen cases in which the pains were referred not to flatfoot itself, but to distant joints, as the knee and even in one case the hip. Or undoubtedly too much medication on general principles for rheumatism is indulged in and Dr. Walsh does well to call attention to it. More careful study of patients is needed and new rheumatic remedies, though so many are being put on the market.

Dr. Webster of Chicago said that the term rheumatism is too often a cloak for hasty diagnosis. If practitioners would study their cases more there would be less supposed rheumatism to treat. It is not enough to relieve pain temporarily, but the root of the trouble must be found and the underlying conditions corrected. Dr. Walsh's cases represent the conditions that are oftenest mistaken for rheumatism. Their treatment constitutes a special problem in each case.

Acromegaly.—Dr. Charles Lyman Greene of St. Paul presented a case of well-marked acromegaly in which the hands were especially involved in the acromegalic condition. Some myxedema is also present. This last condition has been noted in other cases and seems to show that where one ductless gland is affected others may also prove to be in a pathological condition.

SECTION ON SURGERY AND ANATOMY.

SECOND DAY—JUNE 5TH.

The Mortality of Appendicitis.—Dr. John B. Deaver of Philadelphia based his statistics upon 268 cases of appendicitis operated on in the German Hospital in 1900. Of the total in number operated 144 were acute, 124 chronic. He divided the cause of death as follows: (1) Prior to operation; (2) at the time of operation; (3) post-operative. For all cases of appendicitis uncomplicated by intercurrent disease, his statistics give a mortality of 15.9 per cent. In every case the appendix was removed. Of the chronic cases operated upon, but one death occurred, this having been caused by a rupture of an ovarian cyst. His statistics are peculiarly full and reliable because, although occasionally prosecuted he

nevertheless autopsies every case dying in his service. Considering the mortality in general, he said that septic peritonitis is invariably the cause of death. It is induced in a variety of ways, failure to "wall off," or gut obstruction with the formation of adhesions. There is no possible way of assuring one's self which will be the fatal attack although experience shows that they usually increase in severity. Death following operation in chronic cases is due invariably to the factors which may be fatal in any laparotomy. As yet, the fulminating class of cases is lethal despite any promptness of operation.

Technic.—Second only in importance to the extirpation of the appendix is the thorough exploration of the region for hidden pockets of pus. Dangerous in any position, those located in the midline, safeguarded only by the lesser gut, are the most to be dreaded. Operation along these lines insures (1) absence of fecal fistula, (2) subsequent attack, and (3) necrosis of bowel-wall, which is doubtless due to septic embolism of the mesenteric vein. Of eleven cases not operated on in his service three died and six left the hospital with bunches in the right side. Of particular importance is the position of the appendix. When located posteriorly, the termination is not apt to be fatal, because of subsequent ovarian involvement, delay is particularly dangerous in females. Too often normal ovaries have been sacrificed where the appendix was offending. Every death occurring in the second attack must now be recognized to have been preventable. Who must assume the responsibilities of these deaths? Under the term appendicitis is somewhat carelessly grouped a series of protean conditions which give an unusually perplexing and varying number of pathological phases and symptoms. It is a melancholy fact that in every case lost there was a time not taken at the flood. In the absence of true pathognomonic signs, perhaps the best which has yet been recognized is the invariable muscular rigidity over the diseased area. He cited a case which graphically exhibited the importance of this sign and the comparative uselessness of pain. This is in many cases referred to the healthy side. Leading to the fatal goal which is not appendicitis, but rather suppurative peritonitis, there are three sections, *i. e.*, (1) where the inflammation is limited to the appendix, (2) where the abscess is circumscribed, and (3) where septicemia is beginning. Treatment for all conditions lies in the general principle of early operation. In certain conditions continuous irrigation is advised extending at times over a period of four days. From a number of cases it is concluded that salt solution may impede the dissemination of the disease.

Knot Within the Lumen in Intestinal Surgery.—Dr. F. Gregory Connell of Chicago, by a series of exquisite casts, demonstrated his new technic for enterorrhaphy for the prevention of drainage along the needle path. The position of the knot is most important in enteric suturing. It must lie external to the serous surface. Since it cannot be extra-abdominal the only remaining place for it is upon the mucosa. It is here accordingly that his technic places every knot tied. It is an interesting fact that modern surgeons who have written so widely on the value of the submucosa should have overlooked the important writing of Gross of Louisville, who, not alone was well aware of the existence of this layer, but keenly recognized its surgical value. In the classic work of Halsted, in which the layers of the gut were magnified some thirty-three times, the artist failed to give a corresponding increase to the needle. Accordingly in the picture it seems a very simple matter to divide the tissue of submucosa with an ordinary needle. Dr. Connell presented drawings in which a corresponding increase had been made in the size of the needle which laughably demonstrated the impossibility of threading the submucosa. The thickness of this layer is but one-two-hundred-and-fortieth of an inch, the needle being approximately one-fortieth. The particular advantage of his technic is claimed to be (1) less danger of leakage; (2) no yielding; (3) no adhesions; (4) speed.

Dr. Steele of Chicago expressed great pleasure that there existed in this country a hospital where autopsies were made in every fatal case, even at the risk of legal involvement. He added a case to those reported by Dr. Laplace. A child who had swallowed a shawl-pin two and a half months previously presented all the typical symptoms of acute appendicitis. He operated immediately, and found, not the lesion expected, but an abscess caused by the pin perforation. Constant irrigation, which gives such brilliant results in septic joints, must of necessity be of equal value in the abdomen.

Dr. J. B. Murphy of Chicago said that the profession is indebted to Dr. Deaver for the masterly and unflinching manner in which for years he has insisted upon early operation in appendicitis. He asked the following questions: What technically is suppurative peritonitis? Does it signify the accumulation in the body cavity of a cream-colored exudate, or is it rather an abrasion of its shingles, its tesselated layers of endothelial cells? Is not the loss of gloss on the serosa one of the most important indications of this grave condition? Is the relief of tension of as great importance in the abdomen as elsewhere, and is irrigation desirable after operation? Can a diagnosis other than tentative be made of intraperitoneal conditions from the symptoms which are now recognized? After many fatal cases, his faith has been broken.

Dr. Knight of Connecticut emphasized the importance of leucocytosis. He said that the

washing out of the abdominal cavity at the time of operation is infinitely to be preferred to continuous irrigation. Dr. Andrews of Chicago asked, Shall we or shall we not drain or wash out? Probably all cases of so-called general peritonitis are localized. All which are truly diffuse perish. Fowler's position is of the utmost importance. Patients too weak to be otherwise supported, he ties up in bed. The Connell suture is unquestionably the best mode of intestinal anastomosis.

Dr. Moore of Minneapolis said that Dr. Deaver's doctrine in the hands of anyone but Deaver is pernicious and dangerous. Extremists, however, in each direction are absolutely necessary. It is unfortunate that such men should teach. In general practice it is impossible to follow the cast iron rules of Deaver.

Dr. Robt. T. Morris of New York said that principles must be taught students of medicine with as little hesitation as they are expounded to students of law. A priori they would then, in probably all cases be instructed to operate as early as possible. Leucocytosis is of collateral rather than of determining interest. The treatment of appendicitis consists in a relief of the abdominal tension by evacuation and the establishment of conditions favorable to the creation of phagocytes by the organism. Irrigation and packing use up needed strength. Blood-washing, relieving the system with astonishing speed of accumulated toxins, is of far greater importance than abdominal lavage.

Dr. Deaver in answer to Dr. Murphy said that when the serosa is dull and congested, it is safe to feel that the case had passed beyond human help. The relief of abdominal tension is of paramount importance and Dr. Murphy is unquestionably right in saying that no one can as yet establish a diagnosis prior to operation. Experience has taught him, however, that cases in which the belly-walls are tense, where leucocytosis and temperature are absent, where the pulse is elevated, and the onset has been sudden, present the gravest complications. The blood-count is of value only in these very rare instances where leucocytosis is the only factor favoring operation. We must have teachers who are not afraid of their convictions. Early operation is as surely the *sine qua non* of the treatment of appendicitis as there is a God in Heaven.

Teaching of Regional Anatomy.—Dr. Jackson of the University of Missouri described a new method for teaching regional anatomy by sections and drawings. He exhibited a series of specimens which had been prepared by injecting the body with 50-per-cent. formalin, from which his students made tracings of every organ in the body, its relation to its neighbors and to the surface. Decalcification, except where it may be put to the extremely thin sections of the head, is unnecessary. The sole instruments used are a long butcher's knife and saw.

The Nature of the Cancerous Process.—Dr. Roswell Park of Buffalo said that excepting tuberculosis no medical problem has received as much attention as the question of the etiology of neoplastic growth. Among the oldest of the theories was the dietetic. This possesses, of course, but a historic value. The introduction by Cohnheim of the embryological theory marked a very distinct step forward for it explained the presence of certain cells in teratological growth, while not explaining their development. The only remaining theory worthy of consideration is the parasitic. It is not difficult to conceive of an infinitely broad distribution of a body the line history of which is as yet shrouded in mystery. Credence is given to this hypothesis by the interesting relations which observations have shown to exist in many forms both of flora and fauna. To make these observations and to correlate the thousand and one details attendant upon collecting data from every possible source demand the service of the clinician, the pathologist, the histologist and the chemist. He outlined in detail some of the arguments in favor of the protozoic nature of the infection, as follows: (1) In the vegetable world tumors are frequent and are fairly well understood. Many of them eventually destroy their host, this type being known as the tree cancer. Almost invariably of parasitic origin the relation between trauma and growth has in these cases often been observed to be a factor. They occur frequently; for example, at sites where water alternately freezing and thawing has produced a lesion in the tissues. Through this the parasite has entered. (2) Comparatively pathology furnishes data of great value. In the invertebrate numerous tumors have been studied, all of which are undoubtedly of protozoic origin. (3) The infective grunulomata, whose etiology is now so well known, yield to precisely the same sort of treatment as do the carcinomata, furnish one of the strongest argumen s in favor of the parasitic theory. (4) Metastases studies from almost any standpoint likewise give credence to the belief. (5) The auto-infectiousness of carcinoma, which is well known, is another favoring factor. The cancer bodies, so-called, must be one of two series—either they are cell degenerations, or they are parasites. They are never seen, nor can they be produced in any except a cancerous process.

Difficulties Attendant Upon the Research.—Far beyond the border land of any other known scientific explorations, this search into the etiology of cancer carries one into utterly untrodden paths, where laws applicable to the world of bacteriology have but little hold. Koch's laws, for example, which have been used by the opponents of the theory to cast upon it doubt and derision, are very likely in no way applicable to this lowly form of animal life. While it is true to a considerable extent, it has been found possible to conform to them, a number of failures to do so has been one of the strongest factors in the circumstantial evidence that this parasite has but little relation to the bacteria.

Because of the paucity of successful experimental work, accidental clinical explanations are of the greatest value and should always be reported.

Treatment.—While it is yet too early to formulate any rational treatment which shall be directed against the development of this parasite, there is ground to hope that in the not far distant future some drug will be found which, similar to quinine, will terminate its life history.

The Carcinoma Question.—Dr. Nicholas Senn of Chicago said in abstract: (1) The question of the etiology of cancer is the most important medical research of the day; (2) carcinoma results from a typical proliferation of epithelial cells; (3) as carcinoma originates in epithelial cells, it is impossible for it to develop in mesoblastic tissues; (4) histology does not support the parasitic theory; (5) the extension of any tumor to an adjoining tissue is positive proof of malignancy; (6) the increase of carcinoma is more imaginary than real; (7) heredity is a factor which has been much overlooked; (8) age, while rarely over forty, is not unknown below twenty, in which case it is often extremely malignant; (9) seldom follows single injury, often frequently repeated traumas; (10) inoculation has failed to support the parasite theory; (11) direct injection of astringents into the carcinomatous tissues does not stay growth; (12) all sera are worthless; (13) positive cure cannot be claimed until after the twelfth year.

Early Diagnosis of Carcinoma.—Dr. Charles A. Powers of Denver said that it would be trite to outline the need of earliest possible recognition, but about nine per cent. of all cases of carcinoma applying to the surgeon reached him early enough to insure favorable results. It is of the utmost importance that the laity be educated in this matter, as has been done so thoroughly in the case of tuberculosis. The value of blood examinations and of the gastric juice in supposed cases of cancer of the stomach in its latent form are of but little value. Sera are now being produced successfully which in certain latent forms of cancer may have a use similar to tuberculin in tuberculosis diagnosis. This must in our present lack of knowledge rest on clinical observation supported by the microscope. It is questioned by some whether there should be a preliminary microscopal cut. Halsted, for example, says that no tumor should ever be harpooned or cut. On the other hand his colleague, Kelly, does so in every case of cancer.

Mammary Carcinoma.—Drs. W. S. Halsted and J. C. Bloodgood of Baltimore spoke of the multiform varieties of tumors of the breast, which made it difficult to formulate any general law on all of the forms. All forms of breast tumors do not call for removal. From the attitude of general laity it seems impossible at times to follow out one's best judgment and general removal is often demanded. From an examination of the cases occurring at the Johns Hopkins Hospital, 426 in number, 2.4 per cent. were carcinomatous and of these there were 39 per cent. which were operative. When the question of removal is under consideration, the character of the tumor determines the range of the operation. Some do not call for removal at all. Others demand the removal of the tumor at once, and still others that the tumor, as well as a part of the breast should be excised, and in still others, especially when the tumors are multiple and the infection widespread, the muscles of the breast, as well as the glandular and lymphatic structures, should be ablated. Perhaps the most important point with reference to the treatment of the tumors of the breast is the early diagnosis of the condition. Most cases are seen too late and the disease has progressed beyond the point of hopeful prognosis.

Carcinoma of the Cecum.—William J. Mayo of Rochester, N. Y., said that ileocecal carcinoma is not by any means infrequent. Seven per cent. of all malignant growths of the bowel involves the cecum. They may occur at any age and, as is well known, their almost invariable tendency is to form annular constrictions. The duration may often be very prolonged, sometimes to the extent of twelve years. Of the symptoms pain, diarrhea, and tumor, are the most constant and of the greatest diagnostic value. The differential diagnosis from tuberculosis is difficult. Desmoides and impaction of feces are other conditions which occasionally obscure the diagnosis.

Resection of High Rectal Carcinoma.—Dr. Robert F. Weir of New York said that all surgeons were agreed that Kraske's operatoin presents difficulties of technic which are sometimes insurmountable. Especially is this true in the case of high line growths. Maunsell suggested the pulling down of the tumor via the anus, producing a sort of artificial intussusception. The objection to this procedure is that it cannot always be delivered through the dilated and freely incised anus. His operation consists in the opening of the abdomen, in separating the bladder from its attachment to the gut, and in freeing the latter from peritoneum to its last rectal segment. He then ties the middle sacral artery, ligates the gut below the tumor, divides it, carries the tumor and upper gut through the abdominal wound, and removes the tumor. An assistant now passes a delicate forceps through the dilated anus and seizes the two cut margins of the gut, drags them with but little difficulty through the anus, where with perfect freedom a through-and-through anastomosis is made. The reunited gut is without difficulty returned to the pelvis, a drainage-tube is inserted in the perirectal space, and the abdominal wound is closed. Enough cases have not been operated by this method to justify its too warm praise, but in those which Dr. Weir has done it has seemed to him satisfactory in every detail.

Surgical Treatment of Malignant Disease.—Dr. F. S. Dennis of New York said that careful study of life-insurance statistics shows that there has been an appalling increase of cancer

during the past thirty years. Most of these statistics are of recent gathering, as the life of most of the life-insurance companies is still so short that reliable statistics are not as yet correlated. A very striking feature is an enormous increase of this disease in communities which by active emigration have lost the younger elements, leaving the older inhabitants. This naturally is an apparent rather than a real increase. An early excision of the tumor will result in 83 per cent. of cure. Should recurrence occur within three years it is probably a case of reinfection rather than of metastasis. Medicinal treatment is not advisable. Recent reports of the advisability of using thyroid extract are not borne out by large experience. Thyroid may relieve the pain and mitigate the odor, but is not in the least curative. Caustics externally may be indicated in certain restricted cases. Coley's fluid has proven of service in the treatment of sarcoma.

Method of Operating on Carcinoma of the Tongue.—In the absence of Dr. J. Collins Warren of Boston Dr. Christian Fenger of Chicago outlined his method of operating on these cases. He limited his discusssion to those conditions in which the posterior half of the tongue, back as far as the soft palate, was involved. As yet the history of these cases forms but a melancholy chapter of surgical annals. The cures cannot be rated higher than ten per cent. and, if these cases of carcinoma of the tip of the tongue are included in the statistics, it gives a much higher percentage of fatality where the growth is posteriorly situated. A knowledge of the distribution of the lymphatic vessels and glands is here of great importance, as in cancer of the breast; indeed, until this fact is recognized the statistics will not improve. Death invariably occurs in cases not operated upon in from five to eighteen months. No ulcer of the mouth should be allowed to pass without microscopic examination. No antisyphilitic treatment is indicated because of the danger of delay. The two factors most dreaded by patients when they are told that they are to lose the whole tongue are aphonia and maldeglutition. By the introduction of plastic surgery the immense aggregation of scar tissue, which develops under the old method of operating, contracts, fixes the floor of the mouth, and, far more than the loss of the larynx, leads to these grave and distressing sequelæ. The best method of obtaining this flap is by making it doubly pedunculated, loosening it from the neck and transplanting its center bodily over the abraded surface. Of great importance is the resection of the inferior maxilla. Without this the deeper lymphatics cannot possibly be reached.

Dr. Crile of Cleveland advocates the use of delicate clamps which, with finely adjusting screws, can be placed on arteries during the time of operation. His belief is that they do not injure the coats to any dangerous extent.

Dr. Rodman of Philadelphia said that the belief in the parasitic theory of cancer is struggling into life. Until very recently cancer was unknown among the negroes and infants. It is difficult to explain this except by assuming a parasitic cause.

Dr. R. H. M. Dawbarn of New York endorsed Dr. Bloodgood's view of the desirability of immediate extirpation of all breast tumors as soon as seen. In exsections of the tongue, the chief cause of death is shock, which all are now agreed is chiefly due to hemorrhage. He could not agree with Dr. Fenger, who felt that the carotids should not be ligated, because it has been often shown that within a few days so free is the anastomosis that the facials begin to pulsate. Furthermore this ligation does away with the need for tracheotomy. In deaths which occur later the cause is sepsis. As in every case where a clean wound is subsequently to be bathed with pus, he rubs into the tissues a copious amount of aristol. This forms an insoluble albuminate which gives to the organism the same protection from absorption of toxin as is afforded by granulation tissues. He never packs the wound but always irrigates. His patients are left as nearly upside down as possible for weeks. Grafting the stump of the twelfth nerve into the remnants of the tongue probably gives those muscle remnants some power over the epiglottis.

(To be continued.)

AMERICAN PEDIATRIC SOCIETY.

Thirteenth Annual Meeting, Held at Niagara Falls, May 27, 28 and 29, 1901.

(Concluded from Page 878.)

SECOND DAY—MAY 28TH.

Glass Sun Room on City Houses.—By Dr. W. P. Northrup's advice, such a structure has been built on the roof of a private house in New York. It is practically an outdoor playroom, where fresh air and sunlight can be had without the dust and noise and dangers and dirt of the city streets. There is ample protection against March winds, and the playhouse can be used all winter. The family for whom the playroom was built had the satisfaction of seeing their only daughter, formerly a very delicate child, grow well and strong. Physicians should advise the construction of such playrooms where the need exists and the money can be provided.

Duration of Summer Diarrheal Attacks Under Treatment.—Dr. Charles Gilmore Kerley presented an analysis of 555 cases. Ages ranged from three months to four years. A proportion were said to be purely breast fed; but probably very few tenement children answer that description. In some form or under some pretext, other food is almost certain to be used from time to time among this class. Fortunately the cost of proprietary foods prevents their use to any great extent among the

very poor. The cases referred to were brought to the dispensary for treatment because of diarrhea between June and September. Of the total number 80 cases recovered in three days; 168 cases recovered in four to seven days; 79 cases recovered in seven to twelve days; 62 cases recovered in twelve to fourteen days; 11 cases recovered in third week; 58 cases recovered in fourth and fifth weeks; 10 cases recovered in sixth to eighth week; 6 cases recovered in eighth to tenth week; 15 cases recovered in third to fifth months.

Mortality.—Of 499 cases treated to the conclusion of their illness, 10 died—a mortality of but 2 per cent. As several thousand children perish in New York annually from summer diarrhea, the inference is that many of such deaths are preventable.

Management of Cases.—Regardless of the severity of the symptoms, the character or number of stools, duration of illness, or reputed character of diet, the first step is to stop the milk. In these cases there is or soon will be an infected gut; hence the intestines should be made as poor a culture tube as possible. Every case must be treated vigorously whether the symptoms are mild or severe. In 218 autopsies conducted by Dr. Kerley, he learned the futility of attempting to judge the actual condition of the intestine by the symptoms. Coarse lesions are found constantly where none are suspected during life. Having stopped the milk, do not resume its use until the stools approximate the normal. Relapse follows earlier resumption of milk diet. Cereal water is used as a substitute—barley-water usually. If a change is desired, add to barley-water a percentage of mutton-broth or beef-juice. The broths must not be added in too large amounts. Dr. Kerley does not believe in the use of brandy or whisky in these cases. White-of-egg mixtures have been discarded; many children fail to digest them. By the use of carbohydrates, the condition in the intestine is changed from one of putrefaction to one of fermentation, the latter status being less favorable for the growth of bacteria. Dextrinized gruels are useful because they permit a stronger diet to be given. The mother is instructed, where fever occurs, to give cold water sponge-baths for fifteen minutes at a time.

Use of Drugs.—After trials of tannigen, salol, resorcin and many other drugs, treatment by drugs narrows itself down to the use of four agents, calomel, castor oil, bismuth and opium. Calomel is preferred, where there is nausea or vomiting, in doses of $^1/_{20}$ to $^1/_{10}$ grain, repeated. Castor oil is used especially in acute septic cases where prompt cleansing is desired. Bismuth subnitrate is given in 10-grain doses every one or two hours regardless of the age of the child. In order to be of service it must produce black stools. If necessary for the production of the sulphide, one-grain doses of precipitated sulphur are administered with the bismuth. Indications for opium are pain, tenesmus, frequent stools; four to five stools daily are desirable, however. Active laxatives are suitable where there are no stools or insufficient stools.

Irrigation of Colon.—A good measure is always overdone; irrigation of the bowel is an illustration. The cases in which it is of most benefit are those which have a moderate number of green stools, with or without blood. Always ask yourself, Is there something to be removed? Normal salt solution is as good as anything that can be used for the purpose; where blood is coming away, 1 per cent. tannic acid may be added. Lukewarm solutions are preferable; if fever exists, use solutions of 70° F.

Education of Mothers.—The mother needs minute instructions to insure cleanliness and proper care of food, bottle and nipple. Mothers must be told to stop milk and give castor oil with the first signs of intestinal derangement. Sooner or later the municipality will recognize the need of establishing laboratories under proper control, where the poor can be sent to obtain what is needed in the way of milk, gruels, broths, etc. Stations established by private benefaction are inadequate to meet the demand and lack responsible scientific control.

Discussion.—Dr. J. P. C. Griffith added a word of warning against the use of powerful irrigating solutions. In the uncertainty as to the condition of the intestine it is impossible to foretell when harm will result.

Dr. Koplik believes that dextrinized gruel is not indicated until vomiting has ceased. During the first few days albumin water is one of the most useful means of tiding over a difficult period. Besides the purpose of mere irrigation, hot rectal injections serve as stimulants where such are needed. A danger in milk laboratories not under control is that mothers run there and get as many bottles as they please; overfeeding results.

Dr. Buckingham could see no reason for outlawing brandy; in some cases it is useful.

Dr. Holt laid stress on the necessity for rest; babies are tired out by excessive attention. To Dr. Kerley's list of four drugs Dr. Holt would add a fifth—sulphate of magnesia as an initial cathartic.

Dr. Winters agreed as to the prompt discontinuance of milk in summer diarrheas, but had doubts as to the wisdom of substituting cereals. At the Demilt Dispensary the use of cereals alone and in combination with animal broths has been unsatisfactory. Where stimulation is needed, very hot water is the proper thing to use; the avoidance of alcohol is important.

Dr. Rotch asked why it was considered necessary to give anything at all during the

first forty-eight hours, when the alimentary tract will absorb nothing. The tissues cry out to be let alone. Barley-water can scarcely be recommended for its nutritive value, and for the craving of the infant at this time sterilized water will suffice. As to rectal irrigation, why not, before discussing its merits, drop the term "summer diarrhea" and decide whether we are contemplating a condition of fermental diarrhea or one of true ileocolitis. By a modern process, fat-free milk can be had without sugar, but representing a definite amount of proteid. This is better than a preparation of white of egg empirically administered.

Feeding of Premature Infants.—Dr. Charles W. Townsend described the feeding of an incubator baby. The birth was only two weeks premature; nevertheless the weight of the child was only two pounds, twelve ounces, a fact which was explained by the finding of numerous large and small areas of placental necrosis. The incubation was conducted at a temperature of 85° F., maintained by hot water. In such surroundings the child remained for six weeks. Its initial weight was doubled in twelve weeks, and at six months the baby weighed twelve pounds. By pouring off the upper part of a quart bottle of fresh, clean milk allowed to stand five hours, cream was obtained having approximately 10 per cent. of fat. By modification a mixture was obtained having a strength of 0.50 per cent. fat, 4.20 per cent. sugar, and 0.20 proteid; of this mixture one dram was at first administered every hour. For easy calculation Dr. Townsend uses as his proteid constituent white of egg, which closely resembles lactalbumin; white of egg is readily obtained and convenient to weigh. Gradually increasing the strength of the mixture, Dr. Townsend was administering, at the end of the first month, fat 3.50, sugar 5.40, proteid 1.40; of this fourteen drams at a feeding. At three months the mixture contained fat 4.00, sugar 5.60, proteid 1.60. At eight months cereal was added in the form of barley-water or oatmeal-water. Dr. Townsend does not usually give cereal before the sixth, seventh or eighth months. In some cases it is required early, our guides being pallor and loss of weight.

Third Day—May 29th.

Election of Officers.—Dr. W. S. Christopher of Chicago was elected President; Dr. C. W. Townsend of Boston, First Vice-President; Dr. John Dorning of New York, Second Vice-President; Dr. S. S. Adams, Secretary; Dr. J. Part West, Treasurer; Dr. W. L. Carr, Recorder and Editor. Dr. T. M. Rotch was added to the Council of the Society. Dr. David Edsall of Philadelphia was made a member.

Congenital Hypertrophic Pyloric Stenosis.—Dr. Saunders presented a specimen from a child who died at the age of five weeks with the classic symptoms of congenital pyloric stenosis. The baby retained at most two meals, then the whole was vomited. Operation was advised and refused. The specimen shows hypertrophy of the entire muscular wall. Near the pylorus is a large thick ring of cartilaginous feel, which, however, on microscopic examination, reveals no cartilaginous change. The mucous membrane is thrown into thick longitudinal folds.

Dr. L. Emmett Holt advised caution in drawing conclusions from stomachs found contracted after death. Mere contraction with apparent thickening and prominent rugæ is not proof of hypertrophy. Dr. Holt has seen specimens from children from three weeks to three years of age quite as contracted as the one presented to the Society, yet there was nothing the matter with the stomachs; they simply were empty. While in the present case there seems to be pyloric thickening, the logical result of stenosis would be dilatation.

Dr. Saunders said the clinical history was important in the case under discussion; it was a classic history of stenosis. The postmortem findings confirmed the diagnosis. The fact that the usual dilatation did not occur in this case added to its interest.

Monster by Defect.—Dr. A. C. Cotton of Chicago presented a specimen delivered to him by Dr. J. M. Lang. The most marked defect is the shortness of the extremities; at first glance the thighs and arms seem to be wanting. A skiagram reveals but one bone in each extremity—probably humeri and femora. The hands and feet are distally clubbed and partially webbed. The cortical substance of the brain is attenuated as if by pressure, and wide separation of the parietals adds to the suggestion of a previous hydrocephalus. At the umbilicus is an omphalocele with the funis at its upper border.

Growth and Development at Puberty.—Dr. W. S. Christopher presented a series of tables and graphic curves based upon the measurement of over six thousand children in Chicago schools. The data represented a study of stature, weight, height sitting, endurance [ergograph], strength of grip of right and left hand, vital capacity. A careful study of normal rate and range of growth and development will furnish the means for the ready detection of pernicious variations. A puberal exaltation of growth has previously been shown as to height and weight; by these tables a similar exaltation of life processes is shown by a larger variety of measurements. Dr. Christopher called attention to the necessity of employing skilled and reliable assistance in pursuing this class of study. Observations made by teachers in the public schools are absolutely worthless and cannot be made the basis of scientific reasoning.

Etiology and Prophylaxis of Pubescent Morbidity.—An increased rate of growth and

increased development of physical power are characteristic of the puberal period. The sexes differ in the direction taken by this exaltation of life processes. In girls, grip, endurance and vital capacity [volume of expired air] do not increase as rapidly as in boys; on the other hand, girls at this period increase in weight and height more rapidly than boys.

Puberty is a period of great individualization, and calls for a wide range of elasticity in the physical management of the child. It is notable that while at puberty mortality is low, morbidity is high, and the great etiological factor in pubescent morbidity is unbalanced physical development. Neuroses and psychoses are often manifestations of the turmoil of this period. If in a child an excessive development of height or weight overtaxes the organs of nutritive supply, the child is reduced to a condition of vital bankruptcy. Such cases Dr. Christopher treats with rest, improved nutrition and the much-despised shoulder-braces. In treating cases of faulty development we must consider such factors as food-supply, condition of nutritive organs, condition of blood, condition of eliminative organs, type of general metabolism.

Dr. W. D. Booker said that Dr. Christopher's studies would be of incalculable benefit to the profession and the community. The Society will look for further enlightenment from the same source.

Dr. L. Emmett Holt said that for some years it has been his practice to record from time to time measurements of head, chest, height and weight in growing children. By this means attention is promptly called to abnormalities. A physician who notices that a child's chest measurement is small realizes that something is radically wrong in that child's life.

Arsenical Poisoning.—Dr. John Lovett Morse of Boston reported a case of arsenical poisoning in an infant. There was marked irritation of the kidney, with albumin, blood and casts in the urine; loss of weight and pallor of skin indicated a disturbance of nutrition; the spleen was enlarged. The source of the arsenic was found to be the blue lining of the baby's bassinet. When the child was removed to another place its condition began to improve; weight and color became normal, the spleen ceased to be palpable, and the urine lost its abnormal constituents. During the illness a cardiac murmur and venous hum were noticed; these were gradually lost. During convalescence the patient developed an acute coryza, and renal complications developed afresh. The child has recovered from its cold, but albumin and casts continue without, however, giving rise to constitutional symptoms.

Temperature in Terminal Tuberculosis.—Dr. S. S. Adams of Washington said he had been struck with the very wide fluctuations of temperature in the later stages of pulmonary tuberculosis in a series of cases in children from three to eleven years. There were no chills, nor sweats in these cases, no cerebral signs of hyperpyrexia—in short, no evidences of septic complications except leucocytosis. The children seemed comfortable and took food regularly even when the temperatures were highest. Morning temperatures were in many instances too low to be recorded by the clinical thermometer. Typical cases ranged from 96° F. in the morning to 105.6° in the evening. Cavities existed in some of the cases—not in all—but the clinical feature to which special attention was called was uniformly present. While fluctuating temperature is frequently spoken of in the description of similar cases, the immense range of the variations is not usually mentioned.

Dr. J. P. C. Griffith described cases of bronchopneumonia in which showed the same type of temperature; his cases eventuated in tuberculosis, but did not go on to the softening stage. In other instances such temperatures had defied absolute diagnosis; physical signs could not be demonstrated, and the patients proceeded to recovery.

Dr. L. Emmett Holt regarded Dr. Adams' cases as probably complicated with streptococcus infection. Tuberculous processes do not alone cause such temperatures; septic pulmonary processes do, even without a general streptococcic blood-infection.

Measles Complicated by Appendicitis.—Dr. Harold Williams reported a case of measles in which pain and tenderness of increasing severity in the region of the appendix began twenty-four hours after the appearance of the eruption. Dulness and induration were absent; temperature, 104° F. Dr. Arthur Cabot was called in consultation, together with Dr. McCullum, and immediate operation was decided upon. A gangrenous appendix was removed. The temperature fell to normal the following day and did not subsequently rise. The case shows that in a weakly boy of twelve years measles is not a contraindication to operation.

Treatment of Diphtheria of Conjunctiva.—Dr. L. Emmett Holt placed on record a case of diphtheritic conjunctivitis which yielded readily to antitoxin.

Dr. Henry D. Chapin said that after treating five cases of diphtheria of the eye he believed that, while the administration of antitoxin should be resorted to as a matter of routine, local treatment has as much to do with saving the eye as any other measure. In his cases ice pledgets and constant irrigation were used.

Dr. T. M. Rotch did not consider it wise to lay too much stress on local treatment. Such treatment should be carefully followed out, but to neglect the prompt use of antitoxin in every case would be to court unnecessary danger.

Dr. Charles G. Kerley spoke of two cases of diphtheritic rhinitis which occurred in the children of a New York laryngologist. The latter treated them unsuccessfully for four weeks as ordinary catarrh. Constitutional symptoms were absolutely wanting. Cultures showed the presence of the diphtheria bacillus in both nose and

throat. One thousand units of antitoxin were given. The children were cured.

Hemorrhage in the Newborn.—Dr. L. Emmett Holt was once called to see a case where, twenty-four hours after birth, a robust nine-pound baby began to vomit blood. This continued throughout the day at fifteen-minute intervals. The mother had lost a baby two years before on its fourth day from gastro-intestinal hemorrhage and was much alarmed. Dr. Holt began the administration of one-grain doses of suprarenal extract at one-hour intervals. When twelve doses had been given the hemorrhage ceased. A practical obstacle to the long-continued administration of suprarenal extract is puckering of the esophagus; the first few doses, however, are easy to get down. Similar treatment was tried in another case reported to Dr. Holt, but here the baby died of intracranial hemorrhage.

Dr. J. L. Morse said he had tried suprarenal extract in a case similar to Dr. Holt's, but had applied it externally in the form of a powder. The result was negative. Ultimately Monsel's solution was used internally and the hemorrhage ceased.

Possible Infectious Nature of Such Hemorrhages.—Cases of hemorrhage in the newborn, said Dr. Rotch, are frequently not hemophilia, but possibly are infectious. A rise of temperature is not uncommon, though none was present in Dr. Holt's case. Difficulty in the interpretation of the value of therapeutic measures arises from our ignorance of the natural course of the disease. These cases are not necessarily fatal even when complicated with ecchymosis and intraocular hemorrhage. We cannot yet answer the question whether subsidence of hemorrhage means that our drugs are efficient or that the disease has run its course. Nevertheless it would be wise to use suprarenal extract in additional cases.

Dr. J. C. Wilson, in discussing the value of suprarenal extract, described the case of a young man admitted to the hospital with gonorrhea. Obstruction led to the use of the catheter, and the bladder was found to be filled with blood, which was drawn off. Vesical distention with blood recurred, and the patient developed hemoptysis, epistaxis, purpura, these continuing for three days. Suprarenal extract was then given in five-grain doses; bleeding ceased after six doses and recovery followed.

Dr. Holt said that the term hemophilia, as applied to hemorrhages in the newborn, is a misnomer. In hemophilia the hereditary element is the main factor; this condition does not become manifest during the first few weeks of life. Hemorrhage in the newborn is a self-limited disease, but the bleeding does not always cease when it should. In the case reported suprarenal seemed to have had prompt effect.

Sacculated Empyema with Prolonged Temperature.—A baby was admitted to the service of Dr. L. Emmett Holt with gastro-intestinal symptoms. After ten days the temperature suddenly rose to 106° F., and during eleven weeks following fluctuated between normal and 105°. The pulse-temperature ratio remained about 3:1. Pulmonary consolidation was suspected, but physical signs were never definite; slight dulness and râles were detected on both sides alike. Intestinal symptoms were never very marked; but throughout its illness the child had from four to five stools each day. Widal test and search for plasmodia negative. Blood-cultures negative. By passing a catheter sputa were obtained for examination for tubercle bacillus. This method Dr. Holt considers superior to scraping the back of the throat. In the present case no tubercle bacilli were found. Successive blood-counts showed leucocytosis 22,000, 14,000, 11,000. Wasting was progressive. The autopsy revealed muco-purulent bronchopneumonia, adherent pleuræ on both sides, and a sacculated empyema holding two ounces of pus on the diaphragmatic surface of the left lung.

Prolonged High Temperature Without Wasting.—Dr. Henry D. Chapin reported a case of persistent high temperature which was studied in the hospital for two months without positive diagnosis. Every fifth day the temperature rose to 104° or 105° F. Quinine, Warburg's tincture, and Fowler's solution did not influence the fever. Between the exacerbations of fever the child felt perfectly well. Examination of blood and sputa for malaria, typhoid and tuberculosis, negative. After two months the child went home and eventually recovered. Interest in the case resided in the fact that there was no wasting; where fever is due to tuberculosis wasting is an almost invariable accompaniment.

BOOK REVIEWS.

First Aid to the Injured and Ambulance Drill. By H. Drinkwater, M.D. The Macmillan Company, London and New York.

This little primer is compiled from a series of lectures given by the author in "first aid" courses. It is redolent with most useful hints and directions for treatment of various injuries which may happen. The treatment of the subject-matter is very simple and clear. There is a very valuable chapter devoted to the treatment of poisoning by various drugs. The second part of the book is devoted to ambulance drill. Here, very completely, but simply, the author shows the proper methods for removing patients from one place to another, by means of hand litters and ordinary stretchers. The text is very richly illustrated so that one can readily comprehend every portion of it.

This booklet is one of many of its kind, but we are sure that it will prove a most valuable assistance to those interested in "first aid" to the injured.

Infant Feeding in Its Relation to Health and Disease. By Louis Fischer, M.D., Attending Physician to the Children's Service of the German Poliklinik and of the West Side German Dispensary; Professor of Diseases of Children in the New York School of Clinical Medicine, etc. The F. A. Davis Company, Philadelphia.

A somewhat detailed knowledge of the modification of milk and other foods for infants has become a necessity for the general practitioner. He should therefore welcome this work which gathers together the accepted ideas on the subject, and encloses them in small compass. After a concise description of the infantile alimentary tract, breast-feeding, mixed feeding, wet-nursing and weaning, the use of modified milk in health is discussed at some length, including its pasteurization and sterilization. A chapter on nipples and nursing-bottles, and a dietary with recipes for various junkets, gruels, etc., are not untimely. The consideration of feeding in disease covers the modification of foods in constipation, diarrhea, and the other common diseases to which infants are susceptible. Rectal feeding, nasal feeding, and the feeding of incubator-babies and diphtheria-intubation cases fill chapters of practical value. The works of other writers have been freely drawn upon, the author criticizing freely and adding the conclusions from his own experience.

A Medico-Legal Manual. By William W. Keysor, Lecturer on Medical Jurisprudence in the Omaha Medical College and Judge of the District Court, Omaha, Nebraska. Burkley Printing Company, Omaha, 1901.

The author says very well in the preface that works on medical jurisprudence are written seemingly for lawyers rather than doctors. Pages are devoted to the signs of pregnancy, chapters to wounds and a volume to poison. Such a work is of little value to the physician who can always find the information it conveys more amply and accurately stated in special treatises in his library. It is to fill the long felt want of a brief manual which shall convey to the doctor especially the legal points necessary for his calling that the present little book is issued.

The work seems to accomplish its purpose very well. The chapter on "Evidence" is particularly practical and would enable many a physician who is about to be a witness to save himself from being made the sport of a browbeating cross questioner. The chapters on "The Mind Diseased," on "What Constitutes a Mind in Law" and that on "The Identification of Person" are very interesting, condensed statements of large important subjects for which much seeking would have to be done in many books. The book-making and binding is scarcely worthy of the contents of the book.

A Text-Book on Practical Obstetrics. By Egbert H. Grandin, M.D., with the collaboration of George W. Jarmin, M.D. Third Edition Revised and Enlarged. F. A. Davis Co., Philadelphia and Chicago.

In this third edition, the authors have added a chapter dealing with the anatomy of the female organs of generation and with embryology. The aim has been to be as concise as possible with the anatomical description; likewise with embryology which commences with a description of the Graafian follicle and ovum and traces the changes taking place in the ovum following fecundation, down to the time of its casting off at full term.

Labor, both normal and abnormal, is fully described and the mechanical principles involved are well brought out. The method of procedure in abnormal cases is made perfectly clear and the student is easily able to grasp the situation intelligently from the rules laid down. Considerable space has been devoted to the care of the newborn infant which will be appreciated by most practitioners. The normal and pathological puerperium is well described and the methods of conducting it are such as are approved by the foremost obstetricians of the present day.

Under obstetric surgery artificial abortion and induction of premature labor are described, also forceps, version, symphysiotomy, Cæsarian section, embryotomy, surgery of the puerperium and ectopic gestation.

The book is well written and should appeal strongly to the student body and general practitioners. The illustrations are good, yet hardly up to the standard. There are 52 full-page plates and 105 illustrations in the text. The book contains about 500 pages.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Atlas and Epitome of Labor and Operative Obstetrics. By Dr. O. Schaeffer. Edited by Dr. J. C. Edgar. 12mo. Illustrated. W. B. Saunders & Company, Philadelphia and London.

Anatomical Atlas of Obstetrics. By Dr. O. Schaeffer. Edited by Dr. J. C. Edgar. 12mo. Illustrated. W. B. Saunders & Company, Philadelphia and London.

New Remedies and Therapeutic Measures. By Dr. J. M. Wainwright. 12mo, 225 pages. G. P. Engelhard & Company, Chicago.

The Acute Contagious Diseases of Childhood. By Dr. M. P. Hatfield. 12mo, 135 pages. Illustrated. G. P. Engelhard & Company, Chicago.

The Optician's Manual. By Dr. C. H. Brown. 8vo, 417 pages. Illustrated. Fourth Edition. The Keystone, Philadelphia.

International Clinics. A Quarterly of Clinical Lectures. Edited by Henry W. Cattell. Vol. I. Eleventh Series. 1901. J. B. Lippincott Company, Philadelphia.

Self-Examination for Medical Students. 3,500 Questions on Medical Subects. Third Edition, Enlarged. P. Blakiston's Son & Co., Philadelphia.

ORIGINAL ARTICLES.

DECORTICATION OF THE LUNG FOR CHRONIC EMPYEMA.*

BY GEORGE RYERSON FOWLER, M.D.,

OF BROOKLYN, N. Y.;

SURGEON TO THE METHODIST EPISCOPAL HOSPITAL; SURGEON-IN-CHIEF TO THE BROOKLYN HOSPITAL; SENIOR SURGEON TO THE GERMAN HOSPITAL.

DECORTICATION of the lung is a term applied to designate a procedure intended to relieve the lung from its environment in cases in which expansion is prevented or interfered with by the presence of a greatly thickened pleural covering. The first operation of this kind on record was done by the writer October 7, 1893†, and reported in the *Medical Record* Dec. 30, 1893. A short abstract of the case is herewith given:

The patient, a female aged thirty-five years, was admitted to my service at the Methodist Episcopal Hospital with a history of having suffered from an intractable chronic empyema of the right side following an attack of grip nearly two years previously. Examination showed a sinus with a depressed external opening lined with integumentary tissue, leading directly inward from the interspace between the fifth and sixth ribs in the axillary line for the distance of about five inches, at which point it terminated in a small cavity. This sinus was the site of a tube drainage which had been instituted two years previously. Many attempts had been made during this time to dispense with this tube, but without success, this invariably leading to a reaccumulation of the purulent fluid and an accession of febrile symptoms. The previous history of the case showed that many attempts had been made to effect obliteration of the cavity and closure of the sinus, including persistent antiseptic irrigation, curetting and stimulating injections, but without result. The physical signs showed that the lung was retracted to the costopulmonary angle above the third rib, the left lung doing practically all the work, with consequent dyspnea upon exertion.

On October 7th an elliptical-shaped incision was made to include the orifice of the sinus, the soft parts cleared, and about 3½ inches each of the fifth and sixth ribs removed. The greatly thickened costal pleura was then revealed firmly attached to the chest-wall and through which the sinus passed in the direction of the median line of the body. Commencing at the site of the opening in the chest-wall, the pleura was isolated by blunt dissection in the direction of the diaphragm until the latter was reached. It was then peeled off from the latter until its limit toward the median line was reached, where it was found to rest against the displaced pericardium, from which, after much difficulty, it was finally detached. This dissection was greatly impeded by the movements of the diaphragm, as well as those of the heart. The dissection was completed by lifting the mass and finally detaching it from the lung above. Considerable expansion of the lung followed at once, and in the course of twenty-eight days this was so far complete that the normal vesicular murmur was present to the level of the seventh rib. The heart had so far receded that its apex beat appeared well to the left of the sternum. This patient is still living and apparently in the best of health. Save for a slight sinking in the chest-wall at the site of the resection of the ribs, there is nothing to suggest the previous existence of an empyema.

The conception of this method of curing an old empyema was entirely original with myself, and was designed for the twofold purpose of permitting, by a formal and radical removal of the greatly thickened and adherent pleura, of the expansion of the lung, as well as the obliteration of a suppurating cavity the existence of which was a serious menace to the patient's health. I was not then aware that Delorme, on April 3, 1893, before the Congrès Française de Chirurgie, had reported some experiments made upon the cadaver with the view of determining the feasibility of such an operation. Delorme's first operation upon the living subject, however, was not performed until January 20, 1894, and was reported before the Académie de Médecine and published in the *Presse Médicale*, Paris, 1894, p. 97, all three of which events took place after the report of my case appeared. In a subsequent study of the subject[2] Delorme does not carry his claim farther back than 1894, and makes no formal claim to priority; although, in the last-named communication, he again reports his own case as "Case I.," reporting mine as "Case II.," suppressing the date of both the operation and report of my case.† Delorme's case succumbed to "cerebral and abdominal tuberculosis, the presence of which was unsuspected," but the operation served, as stated

*Presented to the Section on Surgery and Anatomy, American Medical Association, June 6, 1901.

†The entire credit of this operation is given to Delorme in the most recent publication upon the subject, that of Augros, entitled "Traitement de L'Empyème Chronique par la Decortication du Poumon (Operation de Delorme)." No mention is made in this paper of the dates of my previous operation and report, although the date of Delorme's first operation is specifically mentioned in the following words: "M. Delorme eut l'occasion d'appliquer sa méthode le 20 janvier, 1894, et il en rendait compte en ces termes quatre jours plus tard à l'Académie de médecine." Delorme in reporting his case before the Académie de médecine in January, 1894, used these words; "Le courant, en présence de MM. les médecins principaux Dieu et Nogier, des stagnaires du Val de Grace, de MM. les médecins-majors Gigon, Formegol, avec l'assistance précieuse de M. le professeur agrégé Mignon, du médecin-major Marcus, etc., je pratiquai à ma clinique l'opération suivante."

by Delorme, to illustrate the practicability of decortication.

Delorme records 16 subsequent cases, making 18 in all.‡. Of these one was by Lamotte, a Belgian surgeon; one by Lardy, of Constantinople; one by Sorel, of Havre; one by Djemil Bey, of Constantinople; two by Tavel, of Berne; one by Reclus; three by Guinard; one by Boeckel, of Strasburg; one by Girard, of Berne. In a footnote he refers to two additional cases, one by Roux, of Lausanne, and one by Girard, of Berne. The remaining two cases of the 16 were operated upon by Delorme himself.

The most striking case in Delorme's list is that attributed to Djemil Pasha, which was reported to the Medical Society of Constantinople in 1895. The patient was a "whirling dervish" who had suffered for five months with an extensive pyopneumothorax due to a penetrating wound. The fifth, sixth and seventh ribs were resected and the lung liberated from its environment, after which it immediately refilled the corresponding half of the thoracic cavity. The patient was discharged cured on the twenty-sixth day. Three months afterward he was found to be perfectly well, and able to resume the dance or "whirling" ceremonial of his order.§

Augros, in his paper, follows Delorme's list accurately and gives three additional cases, one occurring in the service of M. Gangolphe, the details of which are supplied by Siraud, his adjunct; and another by Vinay and Jaboulay, and a third by Delagenière.

Dr. Alex. Hugh Ferguson, of Chicago, presented a paper in the Surgical Section of the American Medical Association at the forty-seventh annual meeting in May, 1896, and which was published in the *Journal of the American Medical Association* for January 9, 1897, upon "Thoracoplasty in America and Visceral Pleurectomy, with Report of a Case." He speaks of my operation as the pioneer visceral pleurectomy and refers to three other cases, those of Delorme and Reclus (already referred to) and Gallet (*La Clinique*, June, 1895), and adds one of his own, which was done on December 12, 1895. A careful study of the pathologic changes in this case was made by Dr. Ferguson.

Cestan, in his voluminous work[3] devotes a chapter to decortication, and speaks of the operation as the most recent and interesting contribution to the surgical treatment of empyema. He states that, in its aim it is superior to all other resources. He gives the credit of the new procedure to Delorme upon the basis of the latter's contention that the active expansion of the lung should play a part in the treatment of certain cases of empyema, acknowledging, however, that my case was operated upon and reported prior to Delorme's. Jordan, in an article entitled "Erfahrungen über die Behandlung veraltetes Empyema"[4] reports a case, the first that had been done in Germany. The patient had entirely recovered in 10 weeks.

Verneuil, in an article entitled "La Chirurgie Pleuro-Pulmonaine"[5] refers to Gallet's two cases, citing one as terminating favorably, and one in which an unsuccessful result was reached. Reference is likewise made in this article to the fact that Gallet, in deciding whether or not to operate, is "actuated by radiographs of the lungs." Verneuil likewise states that König and Duplay have both had practical experiences with the operation, and are not disposed to look upon it with favor. Nevertheless, Kocher recommends decortication in the last edition of his "Chirurgische Operationslehre" 1897, and in Duplay's article (Des Fistules Pleurales Succedant a L'Empyème)[6], while he alludes to the operation of decortication only to condemn it, he gives no cases of his own or others.

In a case of empyema of traumatic origin reported by Cestan as having been operated upon by Veslin, the operation was done sixteen months after the injury. In the interval a thoractotomy had been done, which resulted in a fistula, and eight months later Estlander's operation with curettage was followed by no result. The attempt at decortication was only partially successful, the upper third being impossible of detachment. The thoracic flap sloughed, leaving a large opening with exposure of the lung. In the course of the following six months the defect left by the slough had nearly closed and a good functional result was said to have been obtained. Gross[7] attempted the operation in two cases, but the lung and pleura were so fused together that it was found impossible to complete the operation. In one of his cases, he partly removed the pleura, but it remained adherent wherever pleuritic bands had formed. Pascale[8] read a paper at the Congress of Italian Surgeons for 1899 upon decortication of the lung. The paper is largely a résumé of the works of Delorme, Cestan and others. Pascale added five new cases operated upon in 1897 and 1898. Of these four were completely successful; in one a pleural fistula remained. In the discussion upon Pascale's paper Romans stated that he had performed the operation several times, and that it did not always succeed. He cites one case in which expansion of the lung did not follow decortication. Siro likewise reported two personal cases, in which the results were favorable.

The following additional case is introduced, although the result so far as the function of the lung is concerned cannot be as yet stated. The operative features offer some points of

‡ In Cases X. and XII. of Delorme's list the attempt to detach the visceral pleura failed. The first of these was one of Delorme's cases in which Estlander's operation was first performed and an attempt made to decorticate. This was unsuccessful, however, and Schede's operation was finally done. The patient was not cured. The second case was that of Bonilly, who, in a personal communication to Delorme, stated that he had operated once, but was unable to detach the visceral pleura. No further details of this case are given. These are omitted, as decortication was not done either by visceral pleurectomy or visceral pleurotomy.

§ Those who have witnessed the Sem'a of the Mevlevi or Whirling Dervishes, in which a pirouette, lasting for hours, is performed in a circle all around the khanele or ceremonial hall of the convent, with closed eyes and arms outstretched, accompanied by the cries of the dancers in a chant which, together with the whirling, becomes more and more violent as the dance proceeds, will appreciate the completeness of the recovery in Djemil Pasha's case.

special interest, however, and will, perhaps, furnish a sufficient reason for what might otherwise be deemed a premature report:

A male, aged nineteen years, was admitted to the Brooklyn Hospital for an empyema of several weeks' standing. Ordinary tube drainage following the removal of about an inch of rib was instituted. At the end of four weeks the cavity was still discharging copiously, with no disposition on the part of the lung to re-expand. At this time an Estlander's operation was performed, four inches each of the sixth and seventh ribs being removed. At the end of another month it was found that, while the anterior portion of the chest-wall had fallen sufficiently below the normal level to partially obliterate the cavity, the posterior portion had not yielded, and a large cavity still remained, with a dense transverse partition consisting of the greatly thickened visceral pleura forming a floor upon which the base of the lung rested, and which prevented it from descending below the level of the third rib. Posteriorly the visceral pleura was firmly attached at a somewhat higher level than anteriorly, which left a pus cavity the size of a man's fist at this point. Decortication of the lung with total pleurectomy was performed on May 30, 1901. The condition of the patient would not permit of the administration of a general anesthetic for the length of time required for so extensive an operation as would probably be required in the case. In addition to a high degree of leucocytosis and a low hemoglobin percentage and red blood-cell count, the patient was suffering from mitral insufficiency and a high grade of cardiac dilatation. It was, therefore, decided to employ spinal cocainization in the case. The patient proved rebellious, however, and refused to remain quiet for the spinal puncture and injection. To remedy this difficulty, after cocaine infiltration of a small area at the site of the intended puncture, a few drops of chloroform (15 drops in all) were administered, and while under its influence the spinal injection was made, one grain of the cocaine sterilized with chloroform and dissolved in forty minims of sterilized water being employed. Immediately following the injection the head of the table was lowered to facilitate the passage of the cerebrospinal fluid mingled with the cocaine solution to the upper portion of the spinal canal. The analgesic effects of the cocaine injection were most pronounced, both as regards the completeness of the analgesia and its distribution. In a few minutes all parts of the body below the level of the clavicle were absolutely insensitive to pain and the operation was begun.

An obliquely placed, elliptical-shaped incision six inches in length, running parallel with the site of the previously resected sixth rib, and enclosing a large fistulous opening and adjacent granulating surface, was made. At the anterior extremity of this incision, a vertical cut two and one-half inches long was made in an upward direction, and from the posterior extremity a similar cut was made in a downward direction. The two three-cornered flaps thus marked out were dissected from the chest-wall, including the entire thickness of the latter to the ribs. The already existing opening in the bony wall of the chest was then enlarged by the resection of five inches of each of the third, fourth, and fifth ribs. The attempt was made to dissect off the visceral layer of the pleura first, but this was found to be so intimately adherent that it was left until the last, and the costal and diaphragmatic pleura removed first. This was accomplished by the aid of the fingers and blunt scissors without great difficulty, when the strongly adherent costal attachments of the visceral pleura having been loosened, the lung expanded sufficiently to bring the parts well within reach and enabled me to readily dissect the visceral layer of the greatly thickened pleura from the lung, after which the entire mass came away. The two three-cornered flaps were then brought into place and sutured with the exception of a small opening left anteriorly through which was led the projecting end of a gauze tampon which was lightly packed between the base of the lung, which by this time nearly filled the entire right chest, and the diaphragm. The operation occupied one hour and a quarter. The analgesia lasted up to the time of the application of the last three sutures, which the patient felt, otherwise the entire operation was absolutely painless. He left the table in excellent condition, considering the magnitude of the operation, with a pulse below 100 and only suffering moderately from shock. Up to the present time the patient has pursued an uneventful progress toward recovery.

In reviewing the literature of the subject it has developed, so far as my researches go at this time, that the term "decortication of the lung" has been applied to all cases in which the attempt has been made to release the lung from its thickened pleura for the purpose of promoting its expansion. A further and most important purpose is that of removal, as completely as possible, of the entire thickened and degenerated pleura with its septically involved structures, in order to insure rapid healing and early obliteration of the empyemic cavity. The first of these indications may be sometimes fulfilled by visceral pleurectomy with more or less detachment of the adherent and thickened pulmonary membrane, and relatively good results may be obtained by this procedure, even in cases in which the lung does not fully expand at first. So far as I am able to gather this was the method followed by Lambotte, Jordan, Sorel, Djemil Pasha and Bonilly. On the other hand, my own case, Delorme's first case, the two cases

of Reclus, the case of Ferguson, those of Tavel, as well as two subsequent ones of Delorme, were instances of true visceral pleurectomy. That rapid healing and complete recovery may take place with either of these procedures is shown, first, by my own case, in which a prompt operative, as well as functional, result was obtained in four weeks following complete removal of the remains of the pleural membrane; and, second, by Djemil Pasha's case, in which the same prompt result following what, from the description, seems to have been a visceral pleurotomy with simple detachment. It should be stated, however, that in all the cases in which visceral pleurectomy was indubitably performed and recovery took place, both rapid healing and complete re-expansion of the lung was accomplished, while in those instances in which visceral pleurotomy with partial detachment seems to have been done, so far as can be ascertained from the records of the cases, and which survived the operation, four failed of complete expansion and in one the fistulous track remained unhealed. Nevertheless, it cannot be denied that cases will arise, as shown by a study of the cases reported by perfectly competent operators in which difficulties may arise impossible to overcome in attempts to remove entirely all thickened pleura, or even detach the visceral portion. These difficulties are unquestionably increased by the presence of tuberculous deposits in the lung tissue adjacent to or involving the pleural covering. Should these conditions present themselves, it is advisable to discontinue the effort to release the lung.

The indications and contra-indications for the operation, save those which relate to the condition of the chest organs discoverable by physical examination, can scarcely be definitely stated before opening the chest. The thickened pleura may be so intimately adherent as to be impossible of detachment, or it may be detachable and the lung incapable of expansion. Further, the pleura may be peeled off at the visceral reflection, while conditions may be present rendering its complete removal unjustifiable or impossible. Finally, in the most favorable cases, decortication and complete removal may be effected with comparative ease. Upon incising the visceral reflection, if the lips of the incision gape the conditions are favorable for complete detachment of the visceral portion at least, and the effort should be persisted in, even if no expansion of the lung takes place, in the hope that this will take place later on. After detaching the visceral layer, if the hemorrhage has not been excessive and the condition of the patient warrants it, the effort may be made to effect complete removal by attempting to detach the costal reflection, commencing at the site of the resected ribs and following the costal and diaphragmatic portion toward the median line, until the point where the visceral detachment has been affected has been reached.

Ample access to the pleural cavity is to be secured by turning a flap of the soft parts so as to expose two or more of the ribs. The size and shape of this flap will be governed by the position and dimensions of the cavity and the relations of the lung to the thoracic wall. If a fistula exists, at least one, and, if possible, two ribs above this point should be resected. The method of anterior thoractomy through the cartilages advocated by Veslin does not seem to possess any particular advantages. Immediately upon opening the pleural cavity, rapid curettage accompanied by irrigation by means of boric-acid or potassium-permanganate solution should be done. The suggestion of Lambotte to inflate the lung during the operation under general anesthesia is scarcely practicable, although, if this is deemed desirable the patient may be permitted to come out from under the influence of the anesthetic sufficiently to cough. If spinal cocainization is used, as in my second case, the patient may be directed to inflate the lungs at will. Excessive hemorrhage must be kept in check and unnecessary dissection avoided. In incising the visceral pleura, at which point the pleurectomy is generally commenced, care should be exercised not to injure the lung. A small incision to ascertain the thickness of the pleura should first be made, and this subsequently enlarged upon a grooved director. The lung may be recognized by its gray color, and every care should be exercised to avoid penetrating this in the subsequent steps of the decortication. If the lung shows a marked tendency to become herniated at the site of the first incision to an extent to embarrass further manipulation, a second opening may be made and the decortication carried on from this point, instead of enlarging the first. After the incision is once made and the peelings-off process commenced, the fingers of the operator and a pair of blunt scissors are alone needed to complete the decortication. The bleeding is held in check by crowding gauze behind the blunt scissors, or the fingers of the operator, if these are used. By following up the track of the scissors or fingers in this manner surprisingly little blood will be lost. In cases uncomplicated by tuberculous deposits, and particularly where a fistulous track exists passing through a mass of cicatricial tissue and degenerated pleural membrane, the operator may be encouraged to attempt complete removal of the latter. The operation may be completed by light tamponade with gauze and suture of the flap in part. As a part of the after-treatment the patient should be taught to encourage complete expansion of the lung by the use of an apparatus consisting of two large bottles connected together by an inverted U-shaped tube reaching to the bottom of each bottle. Another tube leads into each bottle, through which the pa-

tient forces air upon the surface of the water with which the bottle is filled, thus driving the water from one bottle to the other, and vice versa.

Results.—So far as the present study has developed, the operation of decortication of the lungs, either by visceral pleurectomy, combined visceral, costal, and diaphragmatic pleurectomy, or visceral pleurotomy with detachment, has been attempted or actually performed forty-one times. Three operative deaths have been reported. It is difficult to estimate the actual results so far as restoration of function is concerned, for the reason that, in reporting cases, operators seem to lay more stress upon the operation than the functional result. A study of thirty cases of decortication by one or another of the methods as above stated, and in which these points have been made sufficiently clear in the reports obtainable to base a fair estimate of results upon, shows the following, as viewed from the standpoint of recovery with complete restoration of function of the lung:

Cured	11
Improved	6
Unimproved	9
Died	3
In doubt (my second case)	1

Viewed from the standpoint of cure of the empyema, the following is shown:

Cured	17
Unimproved	9
Died	3
In doubt	1

If we deduct the 6 cases of advanced tuberculosis from the total number, and consider the subject from the standpoint of cure of the empyema, the following appears:

Cured	17
Unimproved	5
Died	1
In doubt	1

Separating the cases of visceral pleurectomy and visceral pleurotomy with detachment, from those in which the diseased portion of the pleura was removed in toto, the following appears:

Visceral pleurotomy and pleurotomy with detachment of the visceral layer (excepting cases of advanced tuberculosis) *22 cases:*

Empyema cured	16
Empyema not cured	2
Operations abandoned	2
Died	2

Total pleurectomy (excision of all accessible diseased visceral and parietal pleural membrane), *2 cases* (both my own):

Completely cured	1
In doubt	1
Died	0

Again, separating the cases of typical visceral pleurectomy from those in which, so far as can be gathered from the reports, the visceral pleura was simply split or incised and the edges of the incision separated so as to permit expansion of the lung, it is found that 7 recovered, so far as the empyema was concerned; but only 3 had a complete functional result, and one died. If we excluded from this list the fatal case of Reclus, in which the autopsy showed extensive tuberculosis of both lungs, and respecting which Reclus states that the operation should not have been attempted, the showing is much better. On the other hand, taking the cases in which pleurotomy with detachment only of the visceral pleura (no portion of the membrane being removed, so far as could be ascertained), and including the cases of advanced tuberculosis, it would appear that 5 were completely cured, 4 were improved, 11 were unimproved and 2 died. Eliminating the tuberculous cases (those in which well-marked evidences of tuberculous deposits were apparent at the operation, or revealed by the autopsy), as well as those in which, after incising the costal pleura, it was found that the visceral pleura was not sufficiently accessible to warrant an attempt to incise it (2 cases), it is found that 5 were completely cured, 4 were improved, 5 were unimproved, and none died. Of the 4 improved cases all had incomplete but improved expansion of lung, but one of them had a persistent fistula.

It would seem from a study of all the available cases that tuberculous disease, either localized (pulmonary) or more or less generalized in addition to the local affection, was responsible for all the deaths, at least half of the failures to cure the empyema and a majority of the cases in which failure to procure complete restoration of the function of the lung resulted.

As to the number of cases in which complete cure, cure of the empyema, or improvement as regards function of the lung, with or without resulting fistulæ, in tuberculous cases, study of the recorded cases gives but unsatisfactory results. With the tendency at the present time to regard the majority, if not all the cases of non-traumatic empyema as tuberculous in origin, it will be claimed that the large majority of the cases included in this study were of that character. In excluding the cases denominated "tuberculous" from consideration in attempting to arrive at the results of the operation of decortication of the lung, care has been exercised to eliminate only those in which the operation or post-mortem revealed such evidences of the disease as should have been discoverable by careful physical examination, examination of the sputum, etc., and in which the lesions were sufficiently extensive as to have deterred a careful operator from attempting the operation, had he been aware of their existence. While it may be true, as claimed, that the chances of escaping tuberculous infection in the lung subjected to such an environment as that which is present in an empyema are in direct proportion to the promptness and completeness

of its functional restoration, yet it must be apparent at a glance that the presence of cavities in the lung involved, or even in the other lung, must necessarily lessen the prognosis in direct proportion to the extent of the lesions, until a point is reached in which the case is absolutely hopeless from the surgical standpoint.

Conclusions.—(1) Decortication of the lung is an operation adapted to all cases of old empyema in which extensive and pre-operatively discoverable tuberculous lesions of the lungs are not present, and in which the patient's condition will permit of a major operation. (2) It may be advantageously substituted for Estlander's operation in the majority of instances in which the latter has been considered, up to the present time, as being indicated, since it is more a rational procedure in that it combines the advantages of restoration of function of the lung, so far as this is possible, with closure of the empyemic cavity. (3) It should replace Schede's operation in all cases. (4) The method by extirpation of the diseased portion of the pleural membrane, including the visceral, cortical, and diaphragmatic portions, is the operation of choice. (5) Failing this, visceral pleurectomy should be selected. (6) Pleurotomy, with simple detachment of the visceral layer of the diseased pleural membrane, gives sufficiently good results to warrant the surgeon in resorting to this procedure in cases in which the condition of the patient will not permit of the application of the other and more desirable methods. (7) Whatever operative method is adopted, as complete access to the cavity of the chest as possible should be obtained, and rapid closure of the opening in the chest-wall afterward secured, since the complete re-expansion of the lung must depend largely upon the normal respiratory movements. (8) Pulmonary or respiratory exercises should not be neglected in the after-treatment, since these aid greatly in the restoration of the function of the lung.

Extradural Spinal Cocainization.—The new method of spinal cocainization proposed by Sicard (*Presse Médicale*, May 11, 1901) has proved its usefulness for medical analgesia, but is inefficient as a measure for surgical anesthesia. It is completely harmless and enables the cocain to be introduced without fail into the extra-dural or epidural space. He calls it "the method of extra-dural injections by the sacrococcygeal route."

A STUDY OF SOME COMPLICATIONS AND SEQUELÆ OF TYPHOID FEVER.

BY H. A. HARE, M.D.,
OF PHILADELPHIA;
PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE AND PHYSICAN TO ITS HOSPITAL;
AND H. R. M. LANDIS, M.D.,
OF PHILADELPHIA;
ASSISTANT IN THE OUT-PATIENT DEPARTMENT OF THE JEFFERSON COLLEGE HOSPITAL.

In April, 1899, one of the writers of this article published an essay on the "Medical Complications and Sequelæ of Typhoid or Enteric Fever," in which he endeavored to present several important facts, the chief of which, perhaps, is that this disease very frequently occurs in forms so varied from that described in text-books that errors in diagnosis are by no means uncommon. A second point of some importance is that this disease, more than any other, seems to be followed by sequelæ near or remote, which are of very great clinical importance. It is an interesting fact that since April, 1899, the literature on this subject has almost equalled that of the previous twenty years, probably because methods of diagnosis are more accurate, physicians are more keenly active in the search for such possibilities, and, finally, because with the aid of two wars involving the Anglo-Saxon race typhoid fever has become very prevalent in camp and in civil life.

In the essay referred to the fact was insisted upon that the prevalence of this disease was continually decreasing all over the world and the percentage of mortality was also decreasing. With the years 1898, 1899 and 1900 there was a great increase in frequency of cases in the great cities of the United States, but notwithstanding this fact there was not only no increase in mortality but an uninterrupted decrease in its percentage which would seem to prove: (1) That many mild cases, which, with faulty diagnosis would have been overlooked, were reported; (2) that the virulence of the disease is decreasing or that the resistance of the race increasing, and (3) that the methods of treatment are greatly improved. That the decreasing death-rate rests upon the development of an immunity seems very unlikely. Personally, we believe, that the modification of the virulence of the infection by improved sanitary measures which are not favorable to the best development of virulence of the specific bacillus is the chief cause of the changes already named.

Passing from these preliminary remarks we may proceed to a study of various interesting facts in connection with the subject of this paper.

Typhoid Fever in Pregnancy.—As was pointed out in the previous essay the pregnant woman suffering from typhoid fever quite commonly aborts, different statistics varying from 70 to 17 per cent., but in many instances no harm befalls either the mother or child.

Morse[1] assigns as the principal cause of abor-

[1] Medical Complications and Sequelæ of Typhoid or Enteric Fever, Lea Brothers & Co.

tion: (1) the high temperature; (2) the accumulation of toxins in the maternal blood; (3) the death of the fetus. The most common cause, however, is belived to be the death of the fetus. It has been shown experimentally that the injection of cultures of the typhoid bacillus into pregnant rabbits and guinea-pigs always results in abortion. A case of typhoid fever complicating pregnancy has recently been reported by Chambrelent[2] and is of very considerable interest. In this instance a woman aged 26 years was taken ill with typhoid fever during the last month of her pregnancy and during the acute stages of the disease was normally delivered of a healthy child; her illness pursuing its regular course and resulting in perfect recovery, while the child manifested none of the symptoms of the malady. Still another case is that which has been recently reported by Dr. Terry, at first privately to one of us, Dr. Hare, and more recently in the MEDICAL NEWS. In this instance a woman of 29 was taken ill with typhoid fever during the fourth month of her third pregnancy. The disease ran a moderately severe course, the temperature 104.1° F. Convalescence began during the fourth week, but the disease did not seem to interfere with the course of the pregnancy nor did the pregnancy seem to influence the disease. The patient went to full term and was delivered of twin girls weighing respectively six and seven pounds which were perfectly healthy in every way.

These instances of typhoid fever complicating pregnancy and resulting in recovery are interesting not only because, as we have already pointed out, the percentage of abortion under these circumstances is usually high, but because, side by side with them we find in medical literature reports of other cases in which the results were by no means so favorable. Thus, de Grandmaison[3] has recently published two cases of a septicemic form of typhoid fever occurring in women during the last stages of pregnancy. In the first, a patient of 20 years, aborted after an illness of a few days. Her temperature then became irregular, and for a period of four weeks stayed constantly between 103° and 104° F. The symptoms during this time were almost entirely abdominal, but toward the last the signs of bronchopneumonia, endocarditis, and peritonitis were present. At the autopsy these various conditions were actually found and the bronchopneumonia was proved to be due to the streptococcus and the endocarditis and peritonitis to the typhoid bacillus. In the second case, a woman delivered at full term, developed typhoid fever a week later. She also suffered from bronchopneumonia and died. At the autopsy there was found an abscess in the right sternoclavicular articulation which was proved to be due to the typhoid fever. The characteristic intestinal lesions were present and the specific bacillus was found in the organs generally although there was also a tuberculous pneumonia. In both of these women the eruption and the enlargement of the spleen were absent. The Widal reaction was present in the second case and the typhoid bacillus was demonstrated in the blood of both. De Grandmaison believes that the abortion in the first case was the direct result of the typhoid and that the septicemic condition was secondary, the infection of the blood taking place from a uterine wound, the recently delivered surfaces offering ready entrance to the general circulation, and so giving rise to septicemia. These cases strongly emphasize the recent remarks of Horton-Smith[4] already insisted upon in our earlier essay, that we must cease considering typhoid fever exclusively an intestinal disease but rather regard it as a form of septicemia.

Typhoid Fever in Children.—Another point of interest that we meet with in the study of typhoid fever is the frequency of the disease in children. That the disease is common in children nothwithstanding the fact that its existence has been denied by many clinicians was we think then proved in the essay to which we have referred. But if any further proof was needed to convince the most doubtful of the fact that typhoid infection in early life is by no means uncommon, such proof is forthcoming in the large number of cases which have been reported within the last two years in which not only numbers of children have been studied when suffering from this malady, but in addition it has been found quite frequently affecting new-born infants. An interesting case of this character showing apparent infection from the mother to the fetus rather than infection of the child by ordinary means after birth is recorded by Chambrelent.[5] In this instance the child gave a positive Widal reaction immediately after birth and also presented symptoms of typhoid fever.

George Blumer[6] records a case of a woman who had typhoid fever four and a half months prior to the birth of her child, the child dying when nine days old as the result of hemorrhagic infection due to the typhoid bacillus. There were hemorrhages in the mucous membrane, a hemorrhagic colitis and an enlarged spleen. Still another instance is reported by Bell[121] of a woman contracting typhoid fever in the eighth month of her pregnancy. She was delivered of an apparently healthy child, but it at once developed a temperature. The child was ill for one week; was markedly jaundiced and had rose spots. The Widal reaction was present on three occasions. Recovery took place. Other remarkable instances are those which have been recently reported by Dr. Morse,[7] who in an extensive review of fetal typhoid found twelve cases in which uterine infection had undoubtedly taken place. Of these nine were born dead or died at birth; two lived four days and one five days. None of the living children showed any symptoms of typhoid fever, they simply did not thrive and died. On examination the spleen and liver were found enlarged in some instances and in others hemorrhages had taken place in various organs. The characteristic lesions of the intestine were invariably absent. This is explained by the fact that the infection in all probability took place through

the placental circulation and not through the mouth. An additional reason is that the intestine is not functionally active at this period of life. Ten cases are cited in which it was evident that intra-uterine infection did not take place, as bacterial examination of the fetus in each instance was negative. Morse believes the high mortality in these cases of intra-uterine infection to be due to the septicemic nature of the disease, and his conclusions are that the bacillus typhosus can pass from the mother to the fetus through the placenta; the fetus usually dies *in utero* or shortly after birth; the fetus may be infected, born alive and die without definite symptoms. It is probably possible for the fetus to be infected *in utero* and be born alive and well. Of this, however, there is no definite proof. The disease undoubtedly is unusual under two years of age, as Morse[8] in a careful review of the question could collect but 18 cases in which the diagnosis was beyond doubt. Nine of these 18 cases were proved by a positive Widal reaction or the finding of typhoid bacilli in the organs. Stowell[9] in a series of 61 cases in children observed the disease in four under two years of age, and Blackader[10] saw it in four cases under two years out of 100. Roemheld in 1898 reported 117 cases in children of whom seven were under 2 years. From 2 up to 15 years the frequency of the disease gradually increases.

The explanation advanced as to the infrequency in the very young is lack of exposure. Stowell states that in nearly every instance the infection was the result of exposure to other children or adults suffering from the disease. Northrup[11] who has seen six cases of undoubted typhoid in children under two years of age states that the diagnosis was easily made on signs and symptoms characteristic of adult typhoid fever. All of his cases were intimately associated with others in the family suffering from the disease and he holds that doubt should be encouraged concerning any diagnosis in an infant under two years not intimately associated with other cases.

Symptoms in Children.—The first manifestation is quite commonly headache which may be quite severe. In 68 of Blackader's 100 cases headache was well-recognized and in 16 was severe. Vertigo may be marked in the beginning. A sudden onset is not infrequent, the child being seized with severe headache and a rapid rise in temperature or by nausea and vomiting. Rarely a convulsion is the first manifestation. Barbier and Herrenschmidt[12] noted vomiting during the prodromal stage in about one-third of 47 cases observed by them. The vomiting does not as a rule continue during the height of the disease although it may return again during convalescence. Sevestra[13] has observed a number of cases which led him to believe that a sudden onset is not very rare. Blackader states that in his experience every case with a sudden onset has been associated with some gastro-intestinal disturbance and attributed to some indiscretion in diet. Epistaxis is present quite as frequently as in adults, occurring in 23 out of Blackader's cases. Among some of the more unusual manifestations at the onset may be mentioned tonsillitis, stomatitis, angina and chills. Anorexia was noted by Blackader in 49 cases. Stowell observed anorexia frequently with gradual failure of the digestive power as the fever increased.

Abdominal pain at the outset is of quite frequent occurrence (33 times in Blackader's series) and is not to be confounded with appendicitis. Richardson[14] has called attention to this point and cites several cases in which operation was urged but in each instance in the course of a few days, typhoid fever became manifest. According to Stowell tympanites is less constant in children than in adults. It was noted as being slightly present in 49 cases by Blackader. Constipation is undoubtedly more common than the typical diarrhea as is shown by a study of these cases. Perforation is extremely rare and is not noted in any of the large series, probably owing to the mildest of the intestinal lesions. French[15] reports a child aged 10 in whom perforation occurred on the fortieth day of her illness. Hemorrhage is also an infrequent accident; in four of Blackader's cases the stools were blood tinged but there was no distinct hemorrhage. Stowell has seen hemorrhage but twice among 61 cases. A palpable spleen was present in 70 per cent. of Blackader's cases and in 69 per cent. of the childent under two years reported by Morse. Stowell states that in the majority of his cases the spleen was enlarged and tender. Enlargement of the liver, though not so marked, is quite often noted. Albuminuria is not unusual and is thought to increase in proportion to the fever. It was not of frequent occurrence in Stowell's series and in his case the specific gravity averaged about 1.020 showing there was very little concentration. Blackader noted albumin in the urine in but five cases presenting an exanthematic eruption, and Weill and Lesieur[16] found albumin in 25 cases.

Temperature in Children.—The course of the fever in children differs essentially from that of adults in that it does not follow the typical curve found in the adult. The rise in temperature may be sudden and abrupt. Usually, however, it rises gradually for the first few days, and then becomes remittent in character, a peculiarity which has given to the disease the name "infantile remittent fever." During the third week the temperature declines rapidly. Stowell[19] has appended several temperature charts to his article showing that the temperature may be extremely irregular in type. Blackader[10] observed in his cases that during convalescence a subnormal temperature lasting for days is a more frequent occurrence than among adults. Janeway[17] states that when typhoid fever breaks out in institutions, especially among children, there are instances in which the fever subsides in from 3 to 10 days. He has designated these cases as typhoid febricula. He has also observed that there is a class of cases, with some gastro-intestinal disturbance and fever without these

manifestations, in whom the fever declines in from one to three days. A short time afterwards regular typhoid fever has developed.

Relapses occur in varying percentages. Blackader noted it in 15 cases while Stowell had but three cases. The degree of infection seems to have no bearing on the frequency with which relapses occur.

Eruption in Children.—The character and site of the eruption does not differ from that of the adult and appears about the same period of the disease. The eruption may first be seen as early as the fourth or as late as the second week, but is usually coincident with the height of the fever. During the third week it fades. Stowell, however, observed typical spots, in a boy four years old, ten days after he was well clinically. Morse found that among 15 cases under two years of age a roseola was present in 13. One would infer from Blackader's statistics that the eruption is not unusually absent as he found it in but 55 out of 100 cases. At times the eruption may be very profuse and occasionally there is an erythematous eruption during the first week. Weill and Lesieur have described an exanthematic form occurring in children. This form of eruption is characterized by large numbers of rose spots, appearing early in the disease and invading the entire cutaneous surface. The spots may be ecchymotic or papular in character. They believe there is some connection between this form of eruption and the mildness or absence of the intestinal symptoms.

While the eruption appears to have some influence on the abdominal symptoms the relationship does not hold with the nervous symptoms which may be quite severe. Among 280 cases they observed 73 with an intense eruption; of these but 15 had noteworthy intestinal symptoms.

Purpura is occasionally seen in children. Pinard[18] reports a boy aged 13 who had hemorrhages from the nose, gums, bowel, and kidneys, and eventually recovered.

Circulatory and Nervous Symptoms.—The effects of the toxins on the circulatory system consist in a gradual weakening of the first sound with the frequent appearance of hemic murmurs. The blood, just as in adults, shows a steadily progressive anemia and diminution of the white cells. M. Guinon[122] has reported the case of a girl, aged fifteen years, who during the first few days of her attack of typhoid fever developed tachycardia and an aggravation of the heart sounds with a dry pericarditis. The pericarditis, for a few days, masked an endocarditis. Pain was present and was increased by pressure. A small and rapid pulse indicated involvement of the myocardium also.

Nervous symptoms are not constant nor do they seem to appear with greater frequency than in the adult, with the exception of apathy which, according to Stowell, is common. Blackader observed nocturnal delirium in 18 cases; drowsiness during the first week in 12; restlessness during second and third week in 15; and in 4 semistupor. Nervous symptoms at the onset often lead to great confusion, especially those cases simulating meningitis. In these the onset is often sudden, with intense headache, retraction of the head, vomiting and delirium. A positive diagnosis is often impossible for a few days when as a rule the condition becomes manifest. The Widal reaction is of little value at this time as it is not commonly found in the early days.

From a review of the literature it is apparent that typhoid fever in children, except in a few details, does not differ essentially from adult typhoid and that the diagnosis in children usually rests on those signs and symptoms on which we place the most reliance in the adult. In children, the course is shorter, varying from 12 to 21 days, and may run even a shorter course. The temperature is either irregular or more often conforms to its own especial type. Abdominal symptoms are not so marked as in the adult and perforation and hemorrhage are extremely unusual. The mortality is greatly below that found in adults except in children under two years of age. In the very young the mortality is very high; thus Morse found 8 deaths out of 17 cases or 47 per cent.

Complications and sequelæ do not seem to be very frequent among children judging from the large groups of cases reported. Stowell mentions varicella, parotitis, bronchitis, pneumonia and hemorrhage. Blackader noted otitis media in four cases, furunculosis in two cases and periostitis in one case. Barbier and Herrenschmidt noted vomiting, febricula of from one to four days' duration and numerous instances of subcutaneous abscesses. Five of their cases developed dysentery as a result of admitting a case of this disease into the ward.

Ryska[19] mentions the only case of cholecystitis occurring among children. The patient was a boy aged thirteen years.

Aphasia has been noted in children, often arising without any ascertainable cause. Samuels[20] reports a child aged 18 months who was aphasic during the last week of its illness. The child made a good recovery. There was a most extreme degree of anemia in this case associated with a high leucocytosis. Da Costa[21] reported a girl who suddenly became aphasic on the fourteenth day. He believed it to be due to toxemia acting on the speech centers or a localized hysteria. Silvio[22] observed aphasia in a child of seven years, the condition persisting throughout the course of the attack. Although there was profound adynamia Silvio believes the aphasia was the result of toxic action on the speech centers.

Of the rarer complications may be mentioned cancrum oris[23] in a child of four; laryngeal stenosis[24] in a boy of nine; typhoidal meningitis in a child of four[25]; and chorea developing in a child of three on the 70th day. An extremely unusual combination is reported by Bell[121]. In a family in which typhoid fever and scarlet fever coexisted one child had scarlet fever, but escaped typhoid fever; another had typhoid fever and

escaped the scarlet fever; a third had typhoid fever primarily and was taken with scarlet fever on the 20th day; a fourth had scarlet fever primarily with typhoidal infection on the 10th day.

Typhoid Fever in Advanced Years.—It has been known by all physicians that typhoid fever in advanced life is an exceedingly dangerous malady. Fatal as it is between 20 and 30, it is more and more fatal as life progresses, while, on the other hand, it is equally well known that typhoid infection in advanced years is comparatively uncommon. It is interesting to note that very few cases in individuals over forty years have been reported among the enormous number collected during the past two years, although from a study of literature it would seem that the statements as to its relative infrequency are too sweeping. Osler in *Studies No. III.* tabulates 52 cases out of 829 occurring beyond the fortieth year; 12 being over 50 years of age. Among those which have been reported we find an instance seen by Dr. Skinner[26] in which a woman of 52 was taken with a sudden rise in temperature and for two days had nausea and vomiting. The abdominal symptoms became especially well marked, the eruption was absent, but the Widal reaction was positive. The bowels were obstinately constipated throughout the disease. The fever ran a prolonged course, lasting for ten weeks, and during convalescence right ulnar neuritis developed which was severe in character and followed by atrophy. As this cleared up, the left ulnar nerve and the right peroneal nerve became similarly affected with slight atrophy of the muscles supplied by the latter.

As illustrating how frequently patients well along in years suffer from serious complications during the course of typhoid fever we may note not only this case of Skinner's but also one which has been recorded by C. G. Roth.[27] His patient, a woman of 52 years of age, had a mild infection running a course of about three weeks. During convalescence she was seized with a chill and bilateral pleurisy; and a few days later had another chill followed by pain in the upper lobe of the right lung with bloody expectoration. After this there were intervals of febrile movement preceded by slight chills. But pleural effusion did not take place into either cavity, and recovery ultimately occurred. Gabbi[28] reports two very interesting and unusual complications in a patient 65 years of age who developed paralysis of the ocular motor nerve and polyuria as the result of typhoid infection and Lugard[29] records an instance of a woman of 52 years of age who died on the twenty-ninth day of the disease suffering from a typhoid myocarditis, a lesion which is by no means uncommon in severe cases at this period of life. A case reported by Etienne[30] had a second attack at 44 and a third at 57 with recovery, and a woman, reported by Hamilton,[31] had typhoid fever when 57; the attack being prolonged by two relapses and the appearance of cholecystitis on the seventy-second day.

Mildness of Onset.—Symptoms of typhoid fever at the onset are often vague and indefinite especially in hospital cases where the patients or their friends are as a rule unable to give an intelligent history. In some instances the typhoid infection is masked by other conditions, and several days may elapse before the true condition declares itself. Ambulant cases may escape attention entirely or a fatal hemorrhage or perforation may be the first indication of the disease. Cases are not lacking in which this mildness, or presence of other symptoms than those of typhoid fever, has masked the true disease. Thus, W. W. Ford[32] reports a man whose illness began two months prior to his admission into the hospital During this time he suffered with weakness, anorexia, malaise, cephalalgia, vertigo, numbness, severe chills and night-sweats, cough and articular rheumatism. On admission he was jaundiced and had a thrombosis of the right popliteal vein. During the three weeks he was in the hospital prior to his death he had recurring chills at which time he always had a pronounced leucocytosis (18,000-30,000). Jaundice steadily became more intense until death occurred. At autopsy the healed lesions of typhoid fever were found in the intestines. The final diagnosis in this case was typhoid fever followed by a general septicemic infection.

R. T. Sutherland[33] had a man under his charge for acute alcoholism who showed every evidence of the disease after the former condition had disappeared. T. Anderson[34] reports a fireman who had been ill with a cough and pain in his chest for three weeks but had been walking about until three days prior to his admission to the hospital. Four days after his admission he had hemorrhage and an attack of vomiting. Ten days later he died. At autopsy numerous ulcers of the gall bladder were found, one of which had perforated, although during life there were no symptoms of peritonitis noted. Still another case of extreme mildness is reported by Posselt[35] of a man suffering from Hodgkin's disease in whom the diagnosis of typhoid was not made until autopsy.

Gabbi[36] reports a woman who in the twelfth day of her puerperium had a slight febrile reaction, which at first looked as though a purgative would remove it. Three days later, however, the patient began to complain of malaise and headache and presented a coated tongue and a rise in temperature and so passed into a well defined attack of the disease. Janeway[17] also speaks of six instances in which the diagnosis rested between typhoid fever and puerperal septicemia. Dr. Potaire,[37] of Paris, has recently called attention to the comparative frequency with which persons suffering from influenza develop typhoid. About the time convalescence seems established there is a sudden rise in temperature and severe headache with the usual typhoid symptoms follow. He contends that the condition is originally influenza from the late appearance of the rose spots. David Harris[38] reports a soldier who was seized with a chill and rapid rise in temperature, and an exam-

ination revealed a croupous pneumonia at the left base. Two days later his throat was examined, owing to a complaint of soreness and a well-marked diphtheritic membrane was discovered. Seven days from the onset of the diphtheria rose-colored spots, enlarged spleen and diarrhea led to a diagnosis of typhoid fever. The man made a good recovery. The author believes that the typhoid was present from the beginning but was masked.

Abrupt and Severe Onset.—In children abrupt onset is much more frequent than in adults, and vertigo, vomiting and chills are not unusual manifestations in this class of cases.

T. K. Muro and C. Workman[39] report the case of a man aged 18 who was suddenly seized with vertigo, headache and pain in the abdomen. The following day he had a pleuritic pain in the left side. In the beginning of his illness the diagnosis was not clear and the stools were not characteristic. Towards the end of his illness he had a profuse intestinal hemorrhage and a good deal of abdominal pain. At autopsy marked thrombosis of the mesenteric veins was found. Dubois-Havenith[40] mentions a man who was admitted to the hospital with a scarlatinal erythema. He had been ill for four days, the illness beginning with sore throat, general malaise and fever. He had all of the characteristic signs of typhoid fever, and at the end of the third week he developed a scarlatina-form rash which gradually faded and the skin underwent desquamation.

Those cases in which the onset simulates meningitis with intense headache, delirium and retraction of the head are scarcely distinguishable from the condition they ape. The Widal reaction is not reliable as it is not usually found so early. Trosier describes a case, the onset being marked by violent headache which persisted and later on developed symptoms of meningitis with ultimate recovery.

The principal variation of the fever at onset is a sudden rather than a gradual rise. Cases in which there is a sudden rise are as a rule associated with a chill or chilly sensation, and occur for the most part in children. Occasionally the onset is masked by another condition. Harris reports a soldier who had a chill and sudden rise in temperature in the course of a croupous pneumonia and diphtheria: as these conditions cleared up typhoid fever became evident showing that it had probably been present since the beginning of the case. Potaire states that cases immediately following influenza are quite apt to begin with a sudden rise in temperature. G. Boody[41] reports a case of inverted temperature occurring in an epidemic in the Iowa State Hospital for Insane. The case was typical of typhoid fever except for the temperature which ran a course below normal, and the pulse and respiration were also below the normal.

Chills.—There is probably no one symptom of typhoid fever that has more frequently led to errors in diagnosis than chills. In the vast majority of cases in which they have appeared the diagnosis of malarial infection has been made, particularly in our own army during the past war. They are often seen not only in the early onset but later in the disease and at the onset of relapse. Osler in *Studies No. III.* noted chilly sensations in 213 cases; in 200 cases there was a marked chill, 93 of these cases having more than one chill. We have collected the following cases since the essay was published.

F. Widal[42] reports six cases of young adults, in five of whom the first manifestation was a chill or chilly sensation and severe headache; the sixth was suddenly seized with nausea and vomiting. In the discussion on the paper three other cases of adults were mentioned in which chills and severe headache or vertigo ushered in the disease.

Blackader mentions chills as the initial symptoms in 12 out of 100 cases of typhoid fever in children and other cases are reported by C. E. Edson[43] and by H. C. Thompson.[44] A chill occuring at any time beyond the onset of the disease is usually significant, pointing to some complication, more or less severe. Osler has previously pointed out this in his *Studies No. II.*, and more recently in *Studies No. III.* has added still more instances.

The septicemic type of typhoid fever is often masked by marked rigors. Instances of this are reported by Ford[45] and Gillies.[46] In some instances as in a case reported by Taylor,[47] chills may occur at intervals during the attack without any definite cause.

In connection with the subject of chills the coincident existence of malaria and typhoid may be considered. As before stated the occurrence of chills has led to an enormous number of mistakes in calling typhoid fever malaria fever. Lyon has made a detailed study of the co-existence of the two diseases. In addition to a case of his own he found 29 other cases in the literature in which the co-existence of the malarial parasite and strong evidence, either clinical, pathological or bacteriological, existed of typhoid fever. Such cases are as a rule more severe than simple ordinary typhoid fever, and the mortality is high, 11 out of 30 dying. Complications are also prone to arise.

Chills may occur at the onset or at intervals throughout the attack. In some instances the malarial paroxysms disappeared during the active stage of the typhoid fever, to reappear again during convalescence. Lyon condemns the term typho-malaria and states that the vast majority of cases in the Southern States in which the combination is thought to exist are in reality either simple typhoid or in some instances irregular continued malarial fever. Thayer who has studied the malarial fevers and typhoid fever most thoroughly in and around Baltimore has seen but two cases in which the combination existed.

Abortive Type.—In the presence of extensive epidemics typhoid fever sometimes, especially toward the end, of the epidemic, runs a very short course, amounting to an abortive form. Children in the great majority of in-

stances, enter their convalescence between the tenth and eighteenth day, and cases are reported in which the seventh day marked the decline of the fever in such patients. It must not be understood that the abortive form begins with extreme mildness; quite the contrary. The disease may begin with great severity and in the course of a week or ten days disappear. In Philadelphia during the winter of 1898-99 there was quite an extensive epidemic of enteric fever following the bringing of large numbers of infected soldiers to the city. During this epidemic there was quite a number of cases running a course which were practically abortive in type. (See Hare's Essay.) E. G. Janeway[17] states that when typhoid breaks out in institutions, especially among children, they are cases in which fever is the principal symptom and that it subsides in from three to ten days. He applies the name of "typhoid febricula" to these cases. Paul Remlinger[45] reports twelve cases of the disease with a rubeoliform or scarlatinaform eruption, four of which were of the abortive type.

Alimentary Symptoms at Onset.—Diarrhea, formerly so prevalent in typhoid fever from beginning to end, is present in not more than half of the cases at the present time. In a report of 250 cases of typhoid fever occurring in Ladysmith, South Africa, David Melville[123] states that in but 5 of them was there diarrhea. Constipation was constant and he states that it is a feature of the disease as met with in South Africa. Constipation at the onset is sometimes replaced by diarrhea if purgatives are administered. Nausea and vomiting are present in quite a large number of cases especially those with a rather rapid or abrupt onset. Vomiting was an initial symptom in 209 of Osler's cases. Anorexia is so generally present that it hardly needs mention, while jaundice as a manifestation of typhoidal cholithiasis is sometimes seen late in the disease or during convalescence. Its presence at the onset is unusual. Ogilvie[49] has reported two cases in which jaundice was present, in one case when first seen and in another it appeared on the fourth day of the disease. In a third case jaundice preceded the typhoid fever and co-existed with it. The last case was in all probability catarrhal in origin. The other cases might have been catarrhal or may have been due to typhoidal infection of the gall bladder. Gall bladder involvement, however, generally first manifests itself during the third or fourth week or during convalescence.

An initial symptom of more importance than any of these mentioned is abdominal pain. The pain may be general or may be located in the right iliac fossa, and the latter cases cause the most difficulty in making a diagnosis. General abdominal pain was noted by Osler in *Studies No. III.* in 227 cases and pain limited to the right iliac fossa in six. In studying 500 cases with reference to pain, McCrae[124] found that in 160 cases the pain was present at the onset. The more severe the pain, the greater is the danger of confounding the condition with appendicitis, peritonitis or enteritis. He cites several instances in which these mistakes were made. When pain is limited to the right iliac fossa, the diagnosis of appendicitis is not infrequently made. Richardson[14] has called attention to this danger and cites several cases in which operation was urged but fortunately postponed. W. T. Bull[125] has reported a case in which this mistake was actually made and G. L. Peabody in the discussion stated that he has seen two such instances. H. A. Hare[51] and Janeway[17] have also drawn attention to this possibility.

Respiratory Symptoms at Onset.—In the previous essay the statement was made that bronchitis was unusual at the onset; Gillies[46] however found it present in 33.4 per cent. of 215 cases reported. Edson[52] found acute bronchitis present at the onset in 54 per cent. of his cases, and believes that it is a symptom of extreme importance in the early stages. He found in many instances that the ordinary evidences of bronchitis were absent but that examination of the lungs showed numerous dry râles. In view of the fact that it is now well known that the Eberth bacillus has a tendency to localize in certain parts, as the gall-bladder and urinary bladder, it seems reasonable to suppose that this localization may take place in the lung setting up a consolidation. Localization in the lung with a consolidation presenting all the signs of a croupous pneumonia has been termed by the French "pneumo-typhoid." One of the writers (Hare) in a previous essay accepted this view, and cited several cases which seemed to bear out the truth of the statement. Osler has also accepted this view and in his *Studies No. III.* gives two cases, one in which typhoid fever was unsuspected till autopsy, and in the second, croupous pneumonia was supposed to be the true diagnosis for the first eleven days. No less an authority than Horton-Smith[53] takes an entirely opposite view. He believes the term to be a bad one and if retained should be understood to mean a pneumonia complicating typhoid fever, and in no sense typhoidal in origin. He states that the pneumococcus can always be demonstrated early in the consolidation but it is not found in the late stage. Furthermore where the pneumococcus and bacillus typhosus coexist, the former must be looked upon as responsible.

Von Stühlern[54] in three cases of pneumonia complicating typhoid fever was able to demonstrate this presence of typhoid bacilli, and the *micrococcus lanceolatus* in the sputum. He calls attention to the fact that in such pneumonias the sputum was decidedly hemorrhagic, an observation also made by Curschmann. Harris[55] mentions a case in which a soldier was attacked by pneumonia, later by diphtheria, and that the typhoid fever became evident as the two conditions cleared up. He believes the typhoid fever was present from the onset. Pneumonia as a complication occurred in 15 out of 820 cases during the past eleven years at the Johns Hopkins Hospital.

Gillies[56] observed pneumonia in 2 out of 129. In ascertaining the cause of death among 315 cases Remlinger[57] found eight cases of broncho-pneumonia and four of croupous pneumonia. Hypostatic congestion at the bases of the lungs occurring during the third or fourth weeks is not unusual but is now properly considered as a result of cardiac deficiency rather than a disorder of the lungs. (For Typhoid Pleurisy see Chapter on Respiratory Conditions in Well-Developed Stage.)

Nervous System at Onset.—Headache is by far the most frequent of the nervous manifestations at the onset and is recorded in most of the reported cases, whether associated with other nervous phenomena or not. In Osler's *Studies No. III.* headache was present in 595 out of 829 cases. In quite a large proportion of children the headache is replaced by vertigo. Actual meningitis while comparatively rare at the onset or indeed at any time during the course of typhoid is often simulated especially in the beginning. A limitation should therefore be made in the use of the term meningitic typhoid, applying it only to those cases which simulate true meningitis. Meningitic typhoid often begins with severe headache, especially in onset, early delirium and retraction of the head. Delirium or stiffness of the neck occurred in 61 of Osler's cases. In the course of a week these symptoms entirely pass off. The confusion is intensified because in the early stages the Widal reaction is commonly absent. A true meningitis will usually show paralysis of one of the special nerves, rigidity of the extremities or convulsive movements.

Among the more rare nervous manifestations at the onset are occipital neuralgia, fleeting pains in the wrists and spine, early delirium and tremor of the hands and aphasia. The aphasia in a case reported by Silvio existed from the beginning and lasted throughout the entire course of the disease.

C. P. Emerson[47] reports a case of an oculomotor paresis occurring on the eighth day. As a rule disturbances of the nerves governing the eye occur much later. In the case reported the paresis was thought to be due to a localized patch of meningitis. In the opinion of E. G. Janeway[17] the mental state is sometimes rapidly altered, probably owing to idiosyncrasies. Conditions simulating mania or melancholia appear and he has seen cases in the early stages of typhoid fever in which the diagnosis of insanity was made. These psychoses are distinct from the mental disturbances which appear later.

Renal Lesions in Onset.—Renal lesions at the onset are not usually met with. Osler in *Studies No. III.* reports two cases with albumin and hyaline and granular casts during the first week of the disease.

"THE PORRO-CÆSARIAN OPERATION" WITH REPORT OF TWO SUCCESSFUL CASES.[1]

BY JAMES H. GLASS, M.D.,

OF UTICA, N.Y.;

SURGEON IN CHARGE OF THE FAXTON HOSPITAL.

JAMES BLUNDELL of London, in his Principles and Practice of Obstetrics, 1834, conceived and recommended the employment, while Storer of Boston in 1868 performed the operation which eight years later, in 1876, was first successfully accomplished by Porro of Pavia and has since been known by the name of the later surgeon. Compared with the older Cæsarian method with its open incision and faulty technic the Porro operation with fixation of the stump in the lower angle of the wound proved to be a great step in advance, becoming, because of its lesser mortality and simplicity of recovery, the recognized treatment of Cæsarian cases. Following closely upon this improvement, in 1882, came the recommendation of Sänger of Leipsic that the uterine wound be completely closed.

The practical application of this proposition

[1] Read before the Medical Society of the State of New York.

(first by Leopold of Dresden) resulted in a still further reduction of mother mortality and the very general adoption of this more conservative method, which with the Porro operation and symphysiotomy have revolutionized the attitude of obstetric surgeons to the operation of craniotomy on the living child until now it is, or should be, an operation of little more than historical interest.

In view of the practically common mortality in well done Sänger and Porro-Cæsarian operations we should I believe reach a definite opinion on two propositions dealing with these operations, viz., (1) that tubal excision without hysterectomy for the purpose of sterilization and interference with future pregnancy is unwarrantable. The first should presume the second step as the organ left is rendered functionless and can only become a source of possible trouble or evil; (2) that we should have a well-defined plan of ovarian conservatism and that in all cases possible, an ovary or its fraction should be left *in situ* since recent study so conclusively shows the value of its secretion in general nutrition, and its preventive influence in the nervous disturbance incident to the early and artificial menopause.

The following indications for the Porro operation as formulated by Howard A. Kelly of Baltimore are explicit and difficult of improvement: (1) Where there is good reason to anticipate sepsis, where, for example, the patient is exhausted from protracted labor, and where manual or instrumental efforts at delivery have been made repeatedly or without due antiseptic precautions; (2) where there is cancer of the cervix uteri; (3) where the uterus contains myomatous tumors which block the pelvis or which cannot be safely removed by myomectomy; (4) where there is an extensive atresia of the vagina; (5) where there are bilateral ovarian tumors and no sound part of an ovary can be found and left; (6) when hemorrhage from the placental site is uncontrollable.

The question of the relative rights of mother and child and the responsibility of the surgeon to these in the various forms of maternal dystocia is an intricate one, which, owing to sentimental considerations, must at times be difficult of decision, as between the so-called Sänger and Porro-Cæsarian operations or the former modified by excision of the tubes or ovaries for the purpose of sterilizing the subject. Some authorities maintain that it should be elective with the mother; others oppose this view diametrically, while yet others have various shades of opinion between these extremes. We believe that circumstances should largely govern in this question, and are of the opinion that if the uterus and adnexa are healthy, although dystocia be absolute, we should urge the conservative operation, while doubting our inclination to deny the appeal of the patient to be protected from future hazardous pregnancies, notwithstanding the arguments that she is mistress of her sexual relations and conceptions, or that she may have had a successful Cæsarian operation before.

In an estimate of the comparative mortalities there seems to have been an increasingly favorable showing in the mother mortality for the Porro operation during the last decade. The statistics of Démelin for the past five years giving a mortality for the Porro operation of about 10 per cent., which is about ⅓ less than that in the Sänger-Cæsarian operation. The fetal mortality for the Porro operation, on the other hand, is greatly in excess of that of the Sänger operation, a fact presumably due (as illustrated by Leopold's cases) to the death of the child before undertaking operation, the condition requiring the Porro operation also being reasonable proof of this proposition. The statistics of selected operators, as for example, Sänger, Leopold, Braun, and Zweifel, showing a mortality of about 8 per cent. cannot, of course, be accepted as criteria for general operators. Neither of the two cases whose histories are appended were in the strict sense of the word Porro operations, but modifications of it. Cases No. I. and II. having been done after the methods advocated by Freund and Baer, respectively.

Case I.—Mrs. E. K., American, age forty-three, married at twenty-three years, has borne five living children, the elder being sixteen, the younger three years of age. Since the first labor the patient has had more or less vaginal discharge with evidences of uterine malnutrition, presumably due to cervical laceration; with the last birth there was some antepartum bleeding with postpartum flooding, the attending obstetrician not suspecting the presence of malignant disease. Prior to and during the present pregnancy, which is supposed to have taken place about December 20, 1897, the patient had an increase of the vaginal discharge, which at times was offensive. Since the fifth month of pregnancy there had been hemorrhages of increasing frequency and severity until I was asked to see her September 15th.

The patient was emaciated and exsanguinated; digital examination revealed a soft mass, filling the vagina, bleeding so actively with manipulation that further examination was deferred to a more favorable occasion. The following day the patient was admitted to Faxton Hospital, Utica, N. Y., where further exploration (confirmed by subsequent microscopical examination) showed the growth to be a carcinoma, probably springing from the cervical canal and invading the vaginal wall posteriorly. The mass was carefully packed about with strips of guaze into the mesh of which powdered ferric-alum had been dusted. This procedure was continued from day to day as it was believed to be safer than immediate excision by cautery or otherwise, in the hope that hemorrhage might be controlled, enabling the patient to recover some of her wasted vitality, and at once prolong the period of gestation, thus improving the dubious prospects for both mother and child

in any operative procedure which might be deemed advisable later on. By this means the patient was carried along until about eight and one-half months of gestation, she meantime having been fed to the point of toleration, improving markedly in nutrition; at this time she had some hemorrhage and it was thought best to remove the mass with the galvanocautery which was done without difficulty, it having desiccated and hardened materially since first coming under observation. Hemorrhage from the cervical canal continued.

It being apparent that delivery *per vias naturales* must in all probability result fatally to the mother from shock and hemorrhage, from unavoidable injury to the degenerated friable cervix and lower segment of the uterus, beside offering the child a lessened propect of life as compared with a Cesarian hysterectomy, this procedure was selected and done. An incision extending from the umbilicus to the pubes was made, the edges of the abdominal wall protected with gauze and the exposed uterus packed off with gauze rolls; both ligaments (the right exclusive of the ovary) were grasped with a long Doyen forceps at the same time pushing the point of the forcep into the cervix for the purpose of controlling the circulation in the uterine arteries; a longitudinal incision in the uterus, avoiding the site of placental implantation, was made through which the delivery of the child (a living female of eight pounds weight) was effected without much hemorrhage. The ligated cord was dropped back into the uterine cavity, the uterus, eventrated, was severed from its attachment to the cervix and ligaments, which were tied and cut short after the method of Clark; the cervix was carefully dissected out, it being necessary to excise one-third of the posterior vaginal wall down to the rectal wall in order to get well outside of all infected tissue. There was apparently no involvement of the bladder or anterior vaginal wall in the diseased process. The cut edges of the vagina and peritoneum were approximated, except for a small opening through which a bit of gauze was brought out into the vagina for drainage, as the field had been decidedly septic. The abdominal wound was closed in the usual way. The patient's reaction not being satisfactory, she was given a pint of normal salt solution in the cephalic vein, after which she made an uneventful recovery, the operative field, except that in the track of the gauze, healing primarily. One year after operation we were unable to make out any iliac or other infected glands or tissues, the patient appearing and declaring herself perfectly well. Six months later, however, the disease reappeared in the trigone of the bladder, rapidly proving fatal as a result of obstructive nephritis.

Case II.—Mrs. S. W., age twenty-five years, Austrian, married. Primipara, admitted to Faxton Hospital having been in labor several days, uterine inertia supervening. Upon examination a sloughing funis presented, implying, of course, a dead child and presumably septic uterus. The patient was found to have a flattened rachitic pelvis with a conjugate diameter of two and one-half inches. Preparations for a Porro-Cesarian operation were made, this course being decided upon in view of the septic parturient canal; the consideration of a craniotomy being excluded upon the same grounds. With the patient in the modified Trendelenburg position, an abdominal incision seven and one-half inches in length was made down to the uterus. As in the previous case, the edges of the incision were protected with gauze and the uterus packed off with gauze rolls. Long Doyen forceps were pushed well into the substance of the cervix on either side for the purpose of catching the uterine arteries and clamped firmly down on the ligaments, as before, excluding the ovary on the right side, with the intention of preserving in a measure, at least, the sexual function and the influence of the ovarian secretion on general nutrition of which now there remains little contention; avoiding the area of placental implantation the uterus was now incised longitudinally without much hemorrhage and the dead child delivered, not without some effort, because of impaction in the narrowed pelvis. The uterus was now rapidly cut away, leaving the lower segment of the cervix; the vessels were closed with catgut, the oozing of the cervical stump controlled after the method of Baer by approximating its edges and covering the stump and bare ends of the ligaments by approximating the peritoneal edges, leaving the peritoneum clean and continuous throughout; after wiping out the cavity with normal salt solution the abdominal wall was closed in the usual way, the patient making an uninterrupted and perfect recovery.

Important questions in a consideration of the technic of the Porro operation are (1) control of hemorrhage, (2) the disposition of the stump or (3) its complete extirpation. The method of circulatory control as practised in the above cases was certainly satisfactory and we believe superior, in that it is more simple and exact than manual compressions or the elastic ligature, either of which methods might interfere with smoothness of technic or, on occasion, become positively obstructive, entailing delay and unnecessary shock. Employment of the method recommended also makes more practicable the excision of the uterus with the placenta intact, a consideration of manifest importance in septic uteri, as detachment and delivery of the placenta adds one step more to a serious operation and necessarily endangers an extension of infection. As to the disposition of the cervical stump, its fixation in the lower angle of the abdominal wound, as originally done by Porro, is an almost obsolete practice and justly so as nothing is added to the safety of the operation by so doing and convalescence is delayed. Excision of the cervix after the manner of Freund, except to meet some special indication, would seem undesirable as the integrity of the vaginal vault is impaired, while the additional time consumed and hemorrhage risked from the vaginal blood supply in its accomplishment may

prove a most disadvantageous factor. Admitting the desirability of treating the stump retroperitoneally, inversion, invagination, or approximation of its edges, becomes perhaps a question of minor importance. The later or Baer method is, however, more generally preferred as this disposition of it is done quickly and exactly and leaves a natural vaginal vault.

THE TREATMENT OF SCARLATINAL NEPHRITIS.

BY CHARLES GILMORE KERLEY, M.D.,
OF NEW YORK;
LECTURER ON DISEASES OF CHILDREN IN THE POLYCLINIC MEDICAL SCHOOL; ASSISTANT PHYSICIAN TO THE BABIES' HOSPITAL, NEW YORK.

A CRITICISM of fairly general application concerning the management of scarlet fever rests in an apparent lack of appreciation of the dangers of kidney complication. If every case of scarlet fever, whether mild or severe, were treated as though nephritis were expected, there would be comparatively few cases.

A child with scarlet fever is not to be considered well when the rash fades, when the temperature falls and the throat takes on a normal appearance. He is not to be looked upon as having recovered until five or six weeks have been safely passed. During the first three weeks of this period the patient must be kept in bed, no matter how well he may feel or how mild the attack may have been. It is extremely difficult to keep an active child who feels perfectly well in bed free from exposure, consequently the temperature of the room should be allowed but slight variation. It should range between 68° and 72° F.

When nephritis develops, whether unavoidable or due to neglect, we are very prone to share the apprehension of the family and overtreat the case. Diuretic drugs and combinations of them, the latter suggesting an intimate acquaintance with the "Latest Literature" columns of some of our medical journals, are given with no little harm in some instances.

Much has been written concerning the treatment of scarlatinal nephritis in the young, evidently from the adult standpoint and not based upon bedside experience with children. The child who has passed through even a moderately severe attack of scarlet fever recovers with weakened heart-muscle, unstable nervous system and assimilative powers considerably reduced. If we are to subject such a patient to repeated purgings, prolonged sweatings and promiscuous drug giving, we will do more harm than the nephritis—a disease which has a tendency to get well of itself. These cases should not be approached with fear and force, but with gentleness and therapeutic moderation. Digitalis is too frequently prescribed as a routine measure. When the pulse is full, rapid and of high tension, as is usually the case, the kidneys are already engorged with blood and digitalis will only do harm. Pilocarpine should only be given in extreme cases, after all other means have failed, when uremia is established or when the patient is in an uremic convulsion—even then, its use is only safe in experienced hands.

Irritant cathartics interfere with digestion and assimilation and reduce the strength of the patient. The same is the case with the diuretic potash salts and other so-called diuretic drugs; as diuretics but little reliance can be placed upon them. In those cases in which prompt action is demanded, they fail us.

What then is to be the management of a case of exudative glomerular nephritis of average severity in a child with such symptoms as puffiness of the eyelids, edema of the feet and ankles, scanty, high-colored urine, fever, headache and perhaps nausea, symptoms which appear ordinarily in three to five weeks after the disappearance of the rash.

The first step refers to the diet. Milk, broths, and thin gruels only should be given. The plain milk diet is not necessary or perhaps desirable. When given exclusively the patient soon tires of it and it will not be well borne by the stomach; as milk is to be our main reliance for some time this must not be allowed. It may be given plain with lime-water or mixed with thin gruel; it may be given peptonized or in the form of junket. I usually order two or three feedings a day of thin gruel well salted, or gruel mixed with a very small quantity of animal broth. Six ounces of barley-gruel mixed with one or two ounces of chicken broth will be found acceptable to the great majority of children. Whey made with rennet to which cream has been added also makes an acceptable change. Alcohol in any form should never be used in any of these cases.

The bowels next require attention. There should be two or three stools daily. This is easily accomplished by the use of small doses of calomel, $^1/_{10}$ grain per hour (until one grain has been given), every third or fourth day, with two to four ounces of citrate of magnesia the intervening days if necessary.

Small doses of aconite, ¼ minim every two hours for a child three years of age, are prescribed usually as a routine measure. Aconite in my hands has proven a very useful drug in this connection. In the dosage suggested it produces a moderate diaphoresis which is what we require. While we do not expect much from aconite as a diuretic, its action in this respect is often surprising. When the aconite fails, hot air is brought into use. The hot air is generated by means of a kerosene lamp to which has been attached a funnel and a one inch tin pipe which has been bent at a right angle in the middle and placed so as to conduct the hot air under the bedclothes. The advantage of the hot air generated in this way lies in the fact that the child can be kept in the same temperature as long as desired. This is not possible by any other means. Hot-water bottles become cold unless watched very carefully and the hot pack and bath can only be applied for a short time. If diaphoresis is not produced, the hot pack is used in connection with

the dry heat. The child is immersed in water at 108° F. and kept there from ten to twenty minutes, hot water being added from time to time to keep the temperature at the point mentioned.

The pack and bath as sometimes used can do much harm. Sufficient care as regards exposure is often not exercised when the child is removed from the pack or the bath. If placed in a bed which has not been properly heated by hot-water bottles, the nephritis will be made worse.

Cupping over the kidneys has never been of any assistance in severe cases.

Hot poultices may be of slight service; they require very close watching, however, and must be changed frequently and not be allowed to cool.

A remedy which stands out prominently superior to all others is the hot-water flushing of the colon. I look upon the colon flushings as being of more value in restoring the kidney function than any other one measure. It may be used with advantage when the urine first becomes scanty as well as when convulsions are threatened or present. For a child three years of age, sixteen to twenty-four ounces of normal salt solution at 110° F. is introduced into the colon by means of a rectal tube which should be inserted at least ten inches. The object, of course, is to have the water retained, and the higher it is placed in the colon the more successful we will be in this respect. If the water is expelled shortly after its introduction, the same amount will often be held if it is reintroduced at once. A pint to a pint and a half every six to eight hours answers best in the majority of instances and will be retained by most patients. The results usually are most gratifying. After from three to five flushings in a stubborn case the kidneys often begin to act and soon there is a fairly free flow of urine. The child must be kept in bed until the urine has been normal for two weeks.

MEDICAL PROGRESS.

Tendon Surgery.—F. S. COOLIDGE (*Annals of Surgery*, 1901, No. 5) advances the following points for guiding the operator in tendon surgery, especially that which concerns the subject of infantile paralysis. The time for doing the operation should always be when the reparative process has come absolutely to a standstill. Massage and electricity should be applied until all progress under them has ceased and when it is precisely evident, what muscles are affected permanently, partially or have escaped. Regard must be had for the proportion between the strength of the muscle to be grafted and that of the muscle lost, and especial care must be taken not to overstretch the muscle grafted. Examples have occurred where by patience the peroneus tertius performed the functions of the tibialis anticus and where the sartorius after a few months made a good extensor instead of the quadriceps. Two weak tendons can be made to supplant one strong one. Muscle substance cannot be successfully grafted one into the other, hence the tendons are the best means of doing this. The suturing can best be done above the annular ligament, although it is possible to perform it below also. The tendon of Achilles has no annular ligament. A tendon can by blunt dissection be carried a long distance before the graft is done, beneath the fascia or the skin. Once a muscle of the calf was carried through the interosseous membrane and grafted upon an anterior muscle of the leg. The end-to-end or the side-to-side method of suture is not very secure, consequently the normal tendon is now split a short distance and the paralysed is carried through it and then sewn in situ. Chromated gut with a life of from four to six weeks ought to answer every purpose and is the best for all-round use. Plaster-of-Paris splints for two months, then massage and protection for two months more, with gradually increasing passive motion, and, finally, active motion finish the treatment.

A Case of Trichinosis.—Puffy face and eyelids with marked pallor in a case of trichinosis observed by GEORGE R. SEARS (*Boston Med. and Surg. Jour.*, May 30, 1901) at first suggested acute nephritis. The skin was hot and dry, forearms and legs swollen, but without edema. Tenderness present in tibiæ, calves, thighs and forearms. Successive blood-counts showed moderate leucocytosis with the following percentages of eosinophiles: 17½, 13, 31, 39, 33, 23 per cent. The temperature curve resembled that of typhoid, highest point 104° F. A piece of gastrocnemius muscle was examined eight days after beginning of pains in legs; myositis was found, but no trichinæ. Ten days later a piece of muscle was removed from opposite leg; thirteen trichinæ were seen in a single microscopic field.

Operation in Typhoid Perforation.—H. CUSHING (*Annals of Surgery*, 1901, No. 5) states that unfortunately in this condition statistics are misleading, because they state only the fact as to the operation and its results without proper regard to the various types of case encountered. In Europe the various authorities teach the doctrine of delay, often till the symptoms are purely those of the consequent peritonitis, which they confuse with those of a perforation. In this country, on the other hand, the attitude of the medical and surgical experts is more and more pronounced toward a very early intervention. Just so soon as the symptom-complex indicates that a perforation has occurred should an exploratory laparotomy under local anesthesia be undertaken. The analogy between this condition and that encountered in appendicitis is striking. Here the earlier the operation the better the results so far as life-saving goes. As in appendicitis so in typhoid perforation there are the cases in a pre-extravasation

stage, the cases in the state of localized peritonitis and the cases of generalized peritonitis, with all the chances for best results in favor of those in which the diagnosis and intervention are had in the earliest possible period. Keeping these facts in mind and ever watching all typhoid-fever patients for any abdominal signs, the attending physicians will be able to call in the surgeon early enough to make the statistics of those saved among all fully fifty per cent. by early exploration.

Nasal Conditions of the Aged.—Five cases are reported by B. Douglas (*N. Y. Med. Jour.*, May 25, 1901) to show that it frequently occurs that marked pathological changes are found in the nasal cavities of old people without giving any important symptoms—at least, comparable with the distress which ordinarily results from similar lesions in younger people. A satisfactory explanation is impossible, but he believes that probably the physiological activity of the nose has been so increased as to overcome the damage from the lesions, or perhaps the lesion with its resulting discharge and reflex pain is, in some way, less active and allows the nose to resume its physiological function. The symptom of pain depends not so much upon the degree of inflammation or circulatory disturbance as upon a certain condition of the nervous structures that are distributed through the nares. In older people when the lesions have developed slowly and without marked mechanical irritation from external causes, it may happen that these people are not neurotic and will never develop any of the usual reflex phenomena. The degree of secretion depends largely upon the activity of the inflammatory process and, hence, if it has been a very slow and chronic affair, very marked changes may finally result without having given previous symptoms of annoying discharge.

Operative Treatment of Uterine Cancer.—Herzfeld (*Wiener med. Woch.*, 1900, No. 49) maintains that it is fallacious to speak of abdominal hysterectomy as a "radical" operation, for the following reasons: (1) The cellular tissue of the pelvis, which is commonly involved, cannot be entirely removed. (2) It is technically impossible to remove all neighboring lymph-glands. Vaginal hysterectomy is regarded by the author as safer than the abdominal operation, the latter procedure, in the hands of Wertheim, showing a mortality of 30 per cent. While vaginal hysterectomy is only palliative in 50 per cent. of the cases operated upon, it is absolutely without danger and in the remaining cases lasting results are obtained.

Amyl Salicylate.—Lyonet (*La Méd. Moderne*, May 22, 1901) proposes amyl salicylate as a substitute for methyl salicylate for the following reasons: (*a*) It is fully as active; (*b*) it lacks the disagreeable odor of the drug formerly used; (*c*) it is no more irritating. Two to three grams are painted over the surface of a rheumatic joint, which is then covered with a sheet of gutta-percha: a rapid diminution of pain and swelling follows. The results of administration by the mouth have been fully as satisfactory as those due to local application.

THERAPEUTIC HINTS.

Chorea.—In treating chorea we must bear in mind that voluntary movements of any kind tend to make the involuntary movements more marked, and that the movements cease during sleep, therefore the more quiet a patient can be kept, the better chance there is of proper nutrition for the body and nervous centers. When the motions are severe, chloral in full dose is probably the best narcotic, especially when given with a bromide. Morphine sometimes is better, but may increase the excitement. Inhalations of chloroform may be useful to get the patient off to sleep. The patient should be given liquid nourishment and stimulants; and frequent spongings to stimulate the skin and calm the patient. Constipation is the rule and requires cascara, aloes, etc. Arsenic is the most used remedy and is certainly of value in the dyspeptic conditions of chorea; it may be assisted by iron in the later stages. Other drugs used are zinc oxide, cannabis, physostigma and conium. In chronic cases the much-recommended change of scene often makes the movements worse and prolongs the attack. Massage may be of considerable value. Chorea in many cases is allied to hysteria; therefore, firm, kindly, moral treatment is called for, the patient being encouraged to control the movements by effort of will.—Ashby and Wright *in "Diseases of Children."*

Blepharitis.—The disease is apt to be obstinate, and it is of great importance to remove the cause. Lack of cleanliness, faulty habits and errors of refraction must be looked after. The edges of the lids must be cleansed thoroughly with soap and water, freed from scales and crusts, dried, and then covered with an ointment of yellow oxide of mercury or of ammoniated mercury. To remove the crusts, soap and water, or borax-water should be applied upon cotton. In the ulcerative form an occasional application of one- or two-per-cent. solution of silver nitrate to the raw spots will prove useful. In severe and long-standing cases it will be necessary to pull out all the lashes and then to apply the treatment given above.—C. H. May *in "Diseases of the Eye."*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 15, 1901

THE AMERICAN MEDICAL ASSOCIATION AND ITS WORK.

THE recent well-attended meeting of the American Medical Association at St. Paul shows better, perhaps, than did meetings held at points more convenient for larger numbers of medical men how deep is the profession's interest in the work of the National organization. The Association has in these latter years risen out of a phase of quasi-provincialism to be thoroughly representative of the best elements of scientific and professional progress in American medicine. This state of affairs is most encouraging. At the beginning of the new century the clearest truth in practical life is that assured success is the outcome only of thorough organization. Many problems await solution in the social and legal relations of the medical practitioner to his clients and to public health. These can not be definitely and properly solved unless the weight of a united medical profession can be brought to bear upon legislation and public opinion.

The most noteworthy feature of the last meeting was the liberal attitude of the President and members of the Association toward that portion of the New York medical body whose defection ten years ago did so much to delay the unification of the profession in this country. The recently adopted opinions are, however, only the result of a just survey of the motives and conditions that prompted the attitude assumed by the New York Society before its enforced withdrawal. The President's acknowledgment of the right-mindedness of the motives that formed the basis for the action of the representatives of the New York medical profession must go far to repair the breach that still exists.

The selection of a New Yorker as President of the American Medical Association and the acceptance of the invitation to hold the next annual meeting at Saratoga must be taken as indices of a successful movement that is to give back to the Empire State her long lost influence in the councils of the National body of physicians. The New York State Medical Association, thanks to the unsparing efforts of certain members, has been growing handsomely in numbers and influence in recent years. The auspicious circumstance of having the annual meeting of the National Association to inspire to renewed efforts should add greatly to its membership and prestige. With the recently adopted scheme of reorganization of the State and National Associations, to cement the union of all the societies composing them and to make their influence available for professional purposes, there seems no reason to doubt that the day of a really united medical profession is at hand.

The new plan of government adopted by the National Association promises by its thoroughly representative character to do away with the petty sectional politics that have sometimes proved a jarring element at annual meetings. The proposed reformation of the code, already under way, encourages the hope that a stumbling-block in the way of certain serious minds as regard membership in the Association will be soon removed. For many years past some of the rules of conduct embodied in the old code have, if taken in their strictly literal signification, been a dead letter Since they have proved a source of disunion, it must be a cause of congratulation on all sides that they are to be modified to meet the change of circumstances and evolution of conditions which make them a relic of the past.

The recent St. Paul meeting was especially

noteworthy for the social relaxation it afforded attending members of the Association. Every year the social gatherings take on a more friendly character and the good effected is quite as much due to the familiar fellowship that reveals the character of coworkers in the same field as to the scientific discussions that mirror recent practical advances in the various specialties. The promise may confidently be held out that visitors to the meeting at Saratoga next year will meet with as pleasant a welcome and will be greeted with social features as attractive and gratifying as any ever provided. That the American Medical Association is about to enter into the fulness of its heritage as a thorough representative of the whole medical profession of the country now seems assured.

PARACENTESIS IN ASCITES.

There is considerable discussion always as to the advisability of evacuating fluid that exudes into serous cavities. With regard to pleuritic fluid there is almost an agreement that it should not be removed by mechanical means, unless it is causing acute symptoms, or has been present a long time and is a source of considerable annoyance. Besides, conservative opinion rather tends to formulate the practical rule that not much pleuritic fluid should be removed at a sitting. As soon as the intrathoracic pressure has been materially lessened so as to relieve disturbance of function, then the rest should be left for natural channels to carry off. Unfortunately this conservatism with regard to the removal of pleuritic fluid has had a distinct influence in molding general opinion as to the treatment of ascites, and often serious harm is done by permitting fluid to collect in the abdomen until pressure is so high as to interfere with the circulation through important abdominal organs.

Much of the hesitation to do early paracentesis abdominis for ascites is due to the fact that the older clinicians, such as Niemeyer, Frerichs, and Bristowe were opposed to it. The popular impression, too, that abdominal tapping is always done as a forlorn hope and the tradition that patients seldom recover after it has been once done have had their influence in delaying the little operation. It is the old difficulty of a vicious circle in the formation of a medical conclusion. The popular impression is due to the fact that abdominal paracentesis was so long delayed in the past that it was really only a last resort. Physicians had very slight hope of affording any permanent relief by it. No matter what the condition that produces ascites it should never be allowed to develop to a degree that causes serious respiratory difficulty. Before this occurs there is always such interference with the function of important organs in the abdomen that the patient's general condition deteriorates markedly and rapidly.

In America we owe the tradition to tap the abdomen early to that distinguished clinician Dr. Austin Flint. As long ago as 1863, he wrote in his clinical report on ascites, "Unpromising as are the majority of cases of ascites, I cannot but believe that as regards the prolongation of life and as much improvement as is compatible with existing structural disease, the success of medical practice would be enhanced by employing less than has been the custom, diuretics, hydrogogue cathartics and depressing remedies, and by resorting earlier than is usually done to tapping." More than twenty years later Professor Flint wrote, "After the added experience of these last twenty busy years, I hold to this same opinion of the advisability of early tapping with a strong conviction of its correctness as based on reason and clinical facts." Flint's well-grounded opinion had its effect on European clinicians and Eichhorst, one of the most conservative of the Germans, insisted ten years ago that "puncture of the abdomen and evacuation of the ascitic fluid must not be left as a last resort, or inevitable injury will be done to important organs."

In the Lumleian lectures last year Dr. Cheadle summed up very well the English opinions on the subject. They are still very conservative but a notable change has taken place in recent years in favor of advising earlier paracentesis for ascites. Dr. Cheadle himself has had none but the most gratifying results from early and, if necessary, repeated tapping.

In hepatic ascites this procedure forms for him now an essential part of the treatment. In ascites due to atrophic cirrhosis where the good accomplished is only transitory and nothing can be hoped for beyond a respite of a few months the early removal of the ascitic fluid enables the patient to live longer in comparative comfort instead of struggling through a shortened life in hopeless, almost unmitigated distress. This same thing is eminently true of that other equally hopeless condition, advanced cancer of the liver with ascites.

Text-books of medicine generally lay too much stress on the use of diuretics and hydragogue cathartics in the treatment of these cases of ascites. Dr. Cheadle suggests that the expression "purged to death" is not infrequently sadly appropriate to the records of cirrhotic ascites. However much good it may do once or twice, purging as a repeated therapeutic method is certainly calculated to do more harm than good.

When ascites is due to kidney lesions moderate continuous catharsis does good, for toxic material must be eliminated. Diuretics are under these circumstances apt to do more harm than good. Stimulation of the diseased kidneys only hastens their degeneration. If intra-abdominal pressure is interfering with their normal circulation at the same time, then the end is not far off.

In a word, early tapping is the indication for ascitic accumulation, as soon as it is evident that fluid is still collecting and primary purgation and diuresis do not affect the condition. The main reason for hesitation in the employment of this remedial measure in former years was the fear of infection producing peritonitis. Recent clinical experience shows that with ordinary precautions this fear is unfounded. Abdominal tapping is often followed by free diuresis, the result of the relaxation of pressure on the kidneys which affects the renal veins more than the arteries and thus causes passive congestion. The general condition at once improves. Some lives will be saved by early and, if necessary, repeated abdominal paracentesis; many will be lengthened and the discomfort of a large number of patients will be greatly mitigated.

THEN AND NOW.

WE are just entering upon the period of the year when medical society meetings are especially frequent. We shall hear much of present-day medicine and of its advances. The fact that this is the opening year of a new century will tempt many to be retrospective. Undoubtedly there is much in the old-time medicine to condemn, but advance in medicine has been so rapid of late years that it will not be long before our own positions in medical science will seem as absurd to others, or even to ourselves, as do those of a century or more ago to the present generation.

From this standpoint of judging others as we would be judged, our summations of medicine aforetime will not be so utterly condemnatory, and there will come the realization that after all the old medicine was the soil, weedy though it was, out of which has come the promising harvest of medical science in our day.

There is a chapter in "The Transit of Civilization" by Edward Eggleston, concerning medical notions in the seventeenth century. It is a far cry, but it touches a not unsympathetic chord that thrills to the gropings of the physician of that time to find something that would do his patient good. There was no therapeutic pessimism abroad. Medical infidelity was unknown. The bother was men believed too easily in the efficacy of remedies. The pendulum of medical opinion was in its inevitable swing at the opposite end to which it is now. One distinguished authority asserted that we could not know more of Nature than Aristotle, nor of therapeutics than Galen, and so the old writers must be studied rather than the case. After a perfunctory examination of the patient's pulse and tongue then hours must be given to the search through Galen for all possible hints as to treatment.

Until the middle of the eighteenth century Galen's famous "theriac," the cure-all, the panacea for every ill that flesh is heir to, and a few others besides, was retained in the British Pharmacopœia. Then it was rejected by a majority of a single vote in the Pharmacopœial Commission. The famous, or infamous, mixture contained 60 ingredients—nearly every known drug in some form or other. The important thing about drugs in those times, however, was not so much their essential properties as those they acquired from being gathered at a certain time of the moon and a certain conjuncture of the planets. There was also the accepted doctrine of a sympathy and antipathy of inanimate things toward certain human natures. Temperaments were carefully scrutinized and it was well known, for instance, that the man of choleric disposition, with iron will, would not stand iron well though his condition might seem to give indications for it. On the other hand, patients of capricious appetite and of shifting ways—of the mercurial nervous temperament, in a word—would not be improved by mercury. Blood purification was the great shibboleth of the quack of the seventeenth century, as it has been from the beginning and as it is even in our vauntedly illumined day.

The cast-off rattles of the rattlesnake were an

almost infallible remedy for pains of all kinds, especially for headaches about the menstrual period and for the pains of parturition. Sometimes they were applied externally with due shaking (and this custom has not yet died out in country places). Sometimes the rattles were crushed and taken internally. At a time when the famous weapon ointment so humorously described by Oliver Wendell Holmes—the ointment that was infallible but had to be applied to the weapon not to the wound—was so popular, almost any absurdity in surgical practice does not seem surprising. Milk was given in large quantities in jaundice, because it was argued that white would neutralize yellow. Potable gold was the remedy reserved for wealthy patients. Metallotherapy, a distinguished Frenchman has called it, the effect being produced not by increasing the deposit of gold in the patient's system, but rather by depleting the plethora of the yellow metal in his pockets. Those were the days of the depleting methods of therapeutics, bloodletting, blistering and the rest, and some of them have not gone entirely out of fashion yet.

Of course we feel ourselves thankful to be free from the incubus of all these medical superstitions. Many of them die hard, however, and live on in modified form even in our enlightened day. Popular medicine is largely made up of beliefs quite as unreasonable as were in vogue two centuries ago. One of the duties of the modern physician is to make scientific medicine better understood. Another is to bear in mind that our present generation is not infallible and that accepted opinions are by no means absolute truths. Medical society discussions will lose in acrimony and gain in value with the realization that our position of the pendulum of medical opinion is by no means the ultimate resting place of either theory or practice. Long ago the wise old Greek father of medicine said, "Life is short and art is long, the occasion is fleeting, experience fallacious and judgment difficult. The physician must be prepared, not only to do what is right himself, but to make the patient, the attendants and the conditions coöperate for cure." After 2,500 years Hippocrates' words are as weighty with practical significance as they were at any time in the history of medicine. They surely represent the best plea for peaceful conservatism in the midst of rational, scientific progress that could well be made and are a precious lesson to the beginning century.

ECHOES AND NEWS.

NEW YORK.

Cornell University Medical College.—The third annual commencement of Cornell University Medical College was held last week. The degree of M.D. was conferred on twenty-six graduates, many of them women.

Smallpox in Suffern.—Dr. Johnson, Secretary of the State Board of Health Commission, has investigated a complaint made by the health authorities of New Jersey to the effect that smallpox was being brought into that State from this State, and that the disease had been traced to Suffern, N. Y. Dr. A. S. Zabriskie is health officer of Suffern, and he was asked some time ago by the State Health Department what the conditions were. He replied that there was no smallpox there, but that there was a number of cases of "Cuban itch." Investigation, however, showed that these cases were in every instance smallpox. Dr. Zabriskie, however, insisted that there was no smallpox. Conditions in Suffern are said to be serious. In one family there are six cases. It is also believed that the disease is being carried not only into New Jersey, but into New York City and other localities.

Columbia University Commencement.—Commencement was held June 12th. The graduation class of this year consisted of 142 students. The honorary degree of Master of Science was conferred upon Dr. George M. Lefferts, Clinical Professor of Laryngology and Rhinology of this University.

Ocular Defects in Applicants at West Point.—No official report has as yet been made by the Medical Examining Board, but in official circles it is said that about 25 per cent. of the young men who presented themselves for entrance examination at the Military Academy were found physically disqualified, mainly on account of defects of vision.

New Brooklyn Post-Office Physician.—Dr. W. H. Clowminzer of Brooklyn has been appointed physician for the Brooklyn Post-Office. This new Federal position has been made on the recommendation of Postmaster Wilson, who not infrequently discovers that some of the employees were in the habit of feigning sickness.

Journal of New York Pathological Society.—In lieu of the former annual volume of Transactions, the New York Pathological Society now issues a journal once a month. The first, a very creditable, number has just been received.

Bequest to St. Vincent's Hospital.—The sum of $2,500 has recently been bequeathed to St. Vincent's Hospital.

Harlem Medical Association.—At its last meeting, June 10th, the Harlem Medical Association elected Dr. Joseph E. Lumbard President, Dr. Edmund L. Cocks, Vice-President; Dr. W. H. Luckett, Secretary, and Dr. W. H. Stewart Treasurer.

PHILADELPHIA.

Fewer Cases of Typhoid.—The epidemic of typhoid fever in the twenty-fourth and thirty-fourth wards has somewhat abated, though a large proportion of recent cases has been from that district. No cause for the outbreak has been discovered.

Sterilized Milk and Ice at Less Than Cost.—The Philadelphia Sterilized Milk, Ice and Coal Society has begun its eighth season of work. The Society furnishes to poor people milk at 5 cents per quart and for infant feeding sterilized milk at 1 cent per bottle.

Obituary.—Dr. Edmund Beale died June 1st at his home on Second street, where he had practised medicine and pharmacy for nearly half a century.—Dr. J. Edward Wright died June 9th of tuberculosis in his forty-third year. He had practised in the southeastern section of the city for twenty-one years.

Building Hospitals Restricted.—The recent Act of Assembly providing that hospitals shall not be erected in built-up sections of cities has been pronounced constitutional and will be enforced. This will interfere with three hospitals now under consideration in this city.

Graduation Exercises, University of Pennsylvania.—The Dental and Medical Societies held their meeting June 11th, the medical reunion concluding with a banquet in Houston Hall, at which Provost Harrison responded to the toast "The University." A portrait of the late Prof. John Ashhurst, M.D., was presented to the University by the Society. Dr. A. N. Gaylord delivered the annual oration before the Dental Society.

Resident Physicians at the Philadelphia Hospital.—Efforts are being made to take the appointments of resident physicians at the Philadelphia Hospital out of the sphere of political influence. This year a competitive examination was held, but instead of the Board electing the residents, the eligible list was sent to the three colleges of the city. The college authorities will select the men best qualified for the place and these will be elected by the Board. Seven men are to be chosen from each of the three colleges. The Woman's Medical College has also secured the concession sought for during some years—the admission of three graduates to the resident staff of the hospital. The experiment of female internes was tried some years ago, but not with satisfactory results.

Treatment of Thermic Fever.—At the meeting of the College of Physicians June 5th, Dr. J. M. Spellisy read a historical review of the cases of thermic fever admitted to the Pennsylvania Hospital. The first recognized case was in 1764, the case being recorded under the diagnosis "drinking cold water," as the cause. The paper was also a study of the evolution in methods of treatment at the hospital. Several points regarding treatment were brought out in the discussion of the paper. Dr. Morris B. Lewis believes there is much to be learned regarding the pathology and treatment of the condition by a study of the blood. Dr. J. C. Wilson advocates the use of infusions of salt solution because of the evidences of auto-intoxication. Dr. F. A. Packard spoke of some features of thermic fever not generally noted in text-books. These are a characteristic, mousy odor, a curious, crooning groan, and a mixture of tonic and clonic convulsions. Lack of serosity of the blood is the probable cause of the symptoms. Dr. James Tyson said that the latter point was the probable explanation of the good results following immersion in cold water, some absorption taking place, and more rapid recovery following than when the patient is simply rubbed with ice.

CHICAGO.

Nurses Graduate.—The commencement exercises of the Woman's Hospital of Chicago, given under the auspices of the Ladies' Board of that institution, took place June 4th.

Wardenship of Cook County Hospital.—Daniel D. Healy has notified President Hanberg of the County Board that he will accept the wardenship of the Cook County Hospital, and it is said that he will supersede the present Warden, James H. Graham, about June 15th.

Addition to German Hospital.—A $40,000 addition to the German Hospital is the project undertaken by Superintendent Burmeister and the Trustees of that institution. The Hospital now has accommodations for 100 patients, and there is a demand for double the quarters available.

Visiting Nurse Association.—During May the Visiting Nurse Association of Chicago cared for 704 patients and made 3,222 visits. In coöperation with the Bureau of Charities provision has been made to send fifty women and children on outings during the summer.

New Physiology Scholarship, University of Chicago.—By the will of Dr. Marie J. Mergler, who died at Los Angeles, Cal., in May, the University of Chicago is to have a $3,000 scholarship of physiology. Dr. Mergler also bequeathed $3,000 to the Woman's Hospital of Chicago.

GENERAL.

New Fellowship Appointment in Johns Hopkins University.—Florence R. Sabin, M.D., has been appointed to the fellowship in the Johns Hopkins Medical School provided

by the Baltimore Association for the Promotion of the University Education of Women.

Case of Plague on an Army Transport.—The War Department has been advised from Nagasaki that the delay in the departure of the transport "Kintuck" from that place had been due to a discovery of a case of plague on board which caused the vessel's detention.

Canteen Resolutions of American Medical Association.—By unanimous vote the American Medical Association adopted a report indorsing the movement for the reestablishment of the army post canteen. The Committee on Legislation, through the Chairman, Dr. H. L. E. Johnson, presented a report reciting the resolutions adopted by the Military Surgeons last week and continuing as follows:

"We have carefully considered the resolution proposed and declare it to be wise and proper and of importance to every citizen of the Republic. The resolution is the outgrowth of careful study and observation by the Medical Department of the United States Army, is concurred in by the commanding officers at the several posts, and is intended to correct serious abuses under the present law which result in drunkenness, desertion, insubordination, dishonorable discharge, crime, poverty, appalling increase in disease and invalidism among the soldiers of the United States Army.

"We find that the experience of the foreign Governments coincides with that of the National Association of Military Surgeons in the necessity for the army post exchange, or canteen.

"We recommend that the American Medical Association adopt the resolution proposed, and that it petition the Congress of the United States to repeal at the earliest moment the objectionable law which prohibits the army post exchange."

The Association adopted the following resolution: "*Resolved*, That this body deplores the action of the Congress in abolishing the army post exchange, or canteen, and in the interest of discipline, morality, and sanitation recommends its reestablishment at the earliest possible date."

Consumptive Immigrants Are Barred.—Immigrants with tuberculosis of the lungs hereafter will be debarred from all ports of the United States regardless of boards of special inquiry, which heretofore have used their discretion in the matter. The order, issued by Superintendent of Immigration Powderly, is mandatory. The Board of Special Inquiry at Ellis Island, after receiving the report on a case of tuberculosis from Dr. G. W. Stoner, chief of the medical division of the immigration service at New York, will merely have to debar the immigrant. The Supervising Surgeon-General of the Marine Hospital Service at Washington has declared that "tuberculosis of the lungs is now considered a dangerous contagious disease." Immigrants with pronounced symptoms of consumption often have been deported. There are a few instances where a child ill of the disease has been permitted to land with its parents; hereafter there will be no more of these. The rule will apply also to alien passengers coming in the first and second cabins. The steamship agents say their companies will be affected very little by the new order, as their ships bring over few unhealthy immigrants.

Hospital Superintendent Removed.—The Superintendent of the Isolation Hospital at Paterson, N. J., has been removed, and the resignation of the head nurse accepted, after an investigation by the Board of Health. One of the complaints was of neglect to fumigate the ambulance, whereby, it was charged, a boy suffering from scarlet fever contracted diphtheria and died.

New Appointment, College Physicians and Surgeons, Baltimore.—Dr. William Royal Stokes, City Bacteriologist in Baltimore, has been elected a member of the faculty of the College of Physicians and Surgeons in that city, and has been given the chair of pathology.

Doctor in "Innocents Abroad."—In reply to an inquiring citizen of Chicago, Mark Twain writes that the doctor in "Innocents Abroad" was Dr. A. Reeves Jackson, a prominent physician of Chicago, who died in 1892.

New Haven Water-Supply.—All of the water-supply of the City of New Haven will by next fall be run through immense filters to be constructed by the New Haven Water Company. The company will spend, it is announced to-night, $1,000,000 in order to perfect the new plant, and will commence to install the filters at once. The supply from the Saltonstall, Lake Whitney, Maltby Lake, and Woodbridge systems will all be run through hugh filtering machines before it enters the city pipes. The experiment is the first of the kind ever tried in Connecticut.

Army Medical Appointments.—The following appointments were made by the President last week: Surgeons of volunteers, rank of major, Simon J. Fraser, Howard A. Grube, Richard S. Griswold, Abram L. Haines, Damaso T. Lainé; assistant surgeons, rank of first lieutenant in the Porto Rico regiment, United States volunteer infantry, S. Moret and George F. Mayers.

Discovery of New Antiseptic.—According to the despatches in the lay press, an important discovery in the science of antiseptics, upon which Drs. Frederick G. Novy and Paul C. Freer have been working for over a year in their respective laboratories, has just been made public. The new antiseptics are organic acid hyperoxides. In a watery solution five one-thousandths of 1 per cent. of active oxygen derived from the hyperoxides is fatal to all bacteria. The hyperoxide which was used for the experiments is benzozlacital, and this, as was shown by experiments on dogs, can be

taken internally in large doses without poisonous effect. The discovery promises to result in still other developments of importance.

Mr. John D. Rockefeller Thanked.—The American Medical Association at its recent meeting adopted resolutions expressing thanks to John D. Rockefeller for his gift of $200,000 for the furtherance of scientific research along medical and surgical lines.

Prevalence of Smallpox in the United States.—According to the Public Health Reports issued May 31, 1901, by the U. S. Marine-Hospital Service 25,355 cases of smallpox occurred in the United States from December 28, 1900, to May 31, 1901. For the corresponding period of 1900 11,448 cases were reported. Of the total 25,355 cases this year 427 died, a mortality of a little over 1.5 per cent. For the same period last year this was over 5 per cent. The ten States showing the greatest figures for 1901 are as follows: Tennessee, 4,296; Kansas, 4,033; Louisiana, 3,228; Minnesota, 3,071; Colorado, 2,197; Ohio, 1,894; New York, 935; Indiana and North Carolina, 834 each; Nebraska, 754.

Changes in Army Medical Service.—The following changes in the stations and duties of officers of the Medical Department are ordered: Capt. Francis A. Winter, assistant surgeon, from Fort Sheridan to Jefferson Barracks, relieving Major Marshall W. Wood, surgeon, who will proceed to St. Louis and assume charge of the medical supply depot to relieve Lieut.-Col. Joseph B. Girard, Deputy Surgeon General; Lieut.-Col. Girard to Vancouver Barracks for duty as chief surgeon of the Department of the Columbia. First Lieut. Chase Doster, to the Twenty-first infantry.

A New Journal of Scientific Medicine.—It is understood that a new journal devoted to the interests of scientific medicine will shortly be forthcoming from Boston. It is reported that it has been placed in the competent hands of Dr. Harold C. Ernst, which is assurance of its high aims.

Sanitarium for Fond du Lac, Wisconsin.—On the 12th inst. the corner-stone of St. Mary's Sanitarium was laid with appropriate ceremonies by Archbishop Katzer. The building, which will cost $50,000, is the gift of John T. Boyle.

"Healers" Certificate.—The International Machinists' Association decided recently that a certificate of death from a Christian Scientist doctor would not be recognized in the future in a claim for death benefits.

Obituary.—Dr. Thomas Bond of London, a well-known surgeon and analyst, committed suicide June 6th by throwing himself from a third-story window of his residence. He had been suffering from melancholia for some time. Dr. Bond was surgeon to the late Mr. Gladstone.

Major Louis S. Tesson, medical director of the Department of Columbia, and post surgeon at Vancouver barracks, died June 7th from apoplexy. He had been sick about one month. Major Tesson was fifty-nine years old, a native of Missouri, and joined the Medical Department of the United States Army twenty-six years ago at St. Louis. He had served at all the important army posts in the United States.

Dr. Maurice Lauren Healy of New York City died at the home of his mother in Plattsburg, N. Y., June 8th. Dr. Healy was born in Plattsburg thirty-seven years ago, and was graduated from the New York University Medical College. For three years he was a lecturer in the Post-Graduate College and was assistant in the Demilt Dispensary.

Dr. W. H. Daly of Pittsburg, Pa., died suddenly June 9th. He was well known as the originator of the "embalmed beef" controversy that led to an investigation after the Spanish-American War. He was born in Indiana County, Penn., July 11, 1842. From 1853-4 he attended a course of lectures in the Jefferson Medical College, but graduated from the University of Michigan in 1866. During the Civil War Dr. Daly was for a time a medical cadet at the Germantown United States Army Hospital and an assistant surgeon in the White Hall, United States Army, and the Savannah (Ga.) General Hospitals. He was one of the medical officers sent to Jacksonville, Fla., to receive the final instalment of prisoners from Andersonville at the close of the war. Upon the termination of his service in the army Dr. Daly settled in Pittsburg, where he practised his profession. He again entered the army when the war with Spain began, and became surgeon upon the staff of Gen. Miles. His field service extended from Tampa to Porto Rico. Dr. Daly was a member of the American Medical Association, Medical Society of the State of Pennsylvania, the Alleghany Medical Society, of which he was Recording Secretary; the Pittsburg Academy of Medicine, and the Mott Medical Club.

Dr. R. H. Chilton of Dallas, Texas, died at his home June 6th. Dr. Chilton was an eminent oculist and had enjoyed a large practice in the southwest for more than twenty-five years. He was about fifty years of age.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Own Correspondent.]

LONDON, June 1, 1901.

THE LONDON POLYCLINIC—A HOUSE OF CALL FOR MEDICAL PILGRIMS—THE LABORATORY OF THE COLLEGES OF PHYSICIANS AND SURGEONS—THE FINANCES OF THE COLLEGE OF PHYSICIANS—THE MANAGEMENT OF THE COLLEGE OF SURGEONS—A COMING REFORMER—MR. ANDERSON CRITCHETT.

THE chief event of medical interest during the past week in London is the festival dinner in aid

of the funds of the London Medical Graduates' College and Polyclinic which was held on May 22d. Some five hundred gentlemen, mostly members of the medical profession, sat down to a banquet of the true British type—overbaked meats which coldly furnished forth the long tables, followed by a sluggish, but unending stream of dismal oratory. But the cause for which so many worthy citizens were content to suffer was felt to be of sufficient importance to justify some sacrifice of comfort. The Right Honorable Arthur Balfour, the Leader of the House of Commons, who was in the Chair, made a powerful but somewhat inappropriate speech, for it was virtually a plea for the endowment of scientific research. Now the Polyclinic has nothing to do directly with research; it has indeed bacteriological and other laboratories, but these are intended purely for instruction. The real object of the institution is to enable men who are in busy practice to bring their knowledge and skill up to date *cito, tuto*, and as far as possible *jucunde*. These men cannot get what they want at the medical schools. There they are in the way and are made to feel that they are in the way; and in any case, it is hardly pleasant for a man who is already actively engaged in the battle of life to sit on school benches among a throng of irresponsible boys.

For many years the need of post-graduate instruction has been keenly felt in this country, and it was to supply that need that the Polyclinic was founded some three years ago. The institution had many obstacles to encounter from the external jealousy of the medical schools (of which there are no fewer than eleven in London), and from the internal jealousies of its own promoters. Of these the most prominent was Mr. Jonathan Hutchinson, who by means of his influence, which is deservedly very great with the profession, and by generous gifts and loans of one kind or another, made the embryo institution viable and helped it into healthy life. But his is a masterful personality, and the work was not accomplished without a good deal of friction. There appears, however, to be every prospect that the Polyclinic will now grow in importance and efficiency. The membership is already about seven hundred; the lectures and demonstrations are well attended, and increasing numbers of general practitioners bring cases for consultation.

The institution is further beginning to fulfil a function of a different, but not less important nature. Before its creation London had to the medical visitor from abroad been little better than a wilderness. There was indeed plenty to see, but it was hard to discover how and where to see it. It was a mighty maze, apparently without a plan; and there was nothing to guide the wanderer in his search. Hence medical pilgrims from America and from the Colonies found it more profitable to visit scientific shrines where the "shows" were better organized. The Polyclinic, in addition to the advantages which it offers to native practitioners, is intended to be a house of call for the pilgrims aforesaid. There they will get all necessary information about the medical sights of London, and they will be put in the way of using their time among us to the most profitable purpose.

Unfortunately the Polyclinic is not yet self-supporting and although the profession has done its part, the public to which appeal has been made more than once has not yet responded very liberally. I believe the financial result of the banquet the other night was a disappointment to the friends of the institution. A sum of fifty thousand dollars was wanted to put it on its feet, but only eight thousand were forthcoming. Every effort had been made to whip up rich men with charitable leanings, and at least two millionaires were present, Messrs. Beit and Lionel Phillips, Hebrew Jews from South Africa, one of whom had the honor of being condemned to death by Kruger's High Court of Justice. Some hope was entertained that these financial magnates would between them give what was required, but the bad food and the bad speaking together were quite sufficient to spoil the most charitable temper.

For some years past the College of Physicians and the College of Surgeons have between them maintained a research laboratory in which much good work has been done. But the College of Physicians, though a powerful body which claims for its Fellows a monopoly of hospital appointments in London and in most of the large cities of England, is not a wealthy corporation and its financial situation has recently become somewhat critical in consequence of the fiscal exactions of a government hard pushed for money to carry on a war which is estimated to be costing now something like sixty thousand dollars an hour. The College has probably a good case in law, but has no funds for the expensive luxury of an action; it therefore prefers to pay, though, in the classic phrase of the immortal author of Pickwick, "sighing like bricks as it lugs out the money." But to do this it has to retrench in other directions, and it has accordingly intimated that it can no longer contribute to the support of the Laboratory. The sister College cannot, or will not, maintain it singlehanded, and unless the British Medical Association comes to the rescue the Laboratory is doomed. But it is extremely doubtful whether the Association will be in a position to help. If the scheme for its reconstitution of which something was said in a previous letter is carried into effect, the British Medical Association will have no money to spare for the furtherance of scientific research, for the whole of its income will be swallowed in the cost of the machinery of administration.

The College of Surgeons is a wealthy body, but it is governed by a coterie of hospital surgeons elected by the Fellows who are only a small fraction of the commonalty which consists of the Members. Over and over again determined efforts have been made to break up the College

oligarchy and establish a representative form of government, but the President and Council rule like the gods of Olympus and let the heathen rage at the foot of the heavenly mountain as they list. From time to time some one professing to be a reformer is elected to the Council, and inexperienced persons look for the dawn of a new day. But it is with College reformers, as with the month of March, according to the proverb: they go in like lions but speedily subside to a lamblike tenderness for abuses. If the reforming conscience shows signs of reawakening, it is lulled to slumber again by a well-paid examinership or two. Immense sums of money have been wasted on bricks and mortar, and the management of the institution is in many ways extravagant. A surgeon whose name is a household word throughout the medical world is reported to be about to stand at the next election which will take place in a few weeks, and rumor credits him with the intention of issuing what will be virtually a wholesale condemnation of the policy of the present administration of the College. He holds that but for the existence of gross abuses, the College would be well able to maintain the Laboratory which is now threatened with extinction. If he carries out his threat, there will be what Sir Lucius O'Trigger calls "a very pretty quarrel," the issue of which would in all likelihood be the reconstitution of the College on a more democratic basis. But the College of Surgeons has been threatened with similar anathemas before now and nothing has come of them. The Council room of the dingy building in that old-fashioned legal rookery known as Lincoln's Inn Fields (where the fields had disappeared even in the spacious times of great Elizabeth) has a wonderful sobering effect on the most perfervid temperament. It needs an exceptionally strong man to put himself in opposition to the heads of his profession, and

Enterprises of great pith and moment
With this regard their currents turn awry.

Mr. Anderson Critchett who was recently appointed Surgeon-Oculist to the King has just retired from the staff of St. Mary's Hospital after twenty years' service. He inherited a great name, but he has proved himself fully worthy of it. In spite of the competition of Pagenstecher, to whom the Princess Christian has sent half of the British aristocracy, Mr. Critchett has had many opportunities of treating the eyes of the "upper ten." He is equally popular with his own profession, and with the higher Bohemia of artists, actors and what a well-known peer calls "writing fellows." He is a sayer of good things as may be gathered from the following story which I find in the *St. Mary's Hospital Gazette* for this month: A man having been jambed in a traction engine was brought to the hospital and admitted. As he was suffering from diplopia, Mr. Critchett's advice was sought. Discovering a paralysis of one of the ocular muscles, he gave him large doses of iodide of potassium. The house surgeon wished to try galvanism. After a few weeks the paralysis was cured, and the diplopia had vanished. The house surgeon asked Mr. Critchett which treatment he thought had cured the diplopia. Mr. Critchett said, "I think we might cry 'honors easy,' for I took him by assault and you by battery."

TRANSACTIONS OF THE FOREIGN SOCIETIES.

French.

PRIMARY SUTURE OF NERVE-TRUNKS AND THEIR FUNCTIONAL RESULTS—CEPHALALGIA IN NEPHRITIS—MASSAGE AND MOVABLE KIDNEYS—INTESTINAL WORMS AND APPENDICITIS.

REYNIER, at the Société de Chirurgie, May 1, 1901, said that contrary to the usual opinion he had become convinced that nerves are susceptible of early suture and very prompt union and restoration of function. Evidently an embryonal tissue formation occurred between the cut ends of the nerve, which did not materially interfere with the function in any way at all. In 1894 Monod reported a patient in whom he had sutured the radial nerve at once and in a few days had found that there was no loss whatever of the motor functions in the extensive group of muscles. In a recent case he had sutured the external popliteal nerve and demonstrated that the sensory functions were hardly interfered with a few days afterward and a month later the motor functions were shown to be normal under electrical reaction tests.

WALTHER in the discussion desired to report a curious observation of his own. An automobile conductor had received a severe sprain of his wrist which soon showed injury of the radial and median nerves. There were sensory and motor damage over the distribution of each and soon the muscles began to atrophy and other trophic symptoms appeared. The joints became rather stiff. This continued with hardly any change, except perhaps a slight improvement for about eight months. At this time an amelioration occurred of such a character as to suggest that union and repair in the torn nerves had taken place. Fourteen months after the accident there was tenderness over the median nerve, but the muscles had regained most of their action although not their strength and the anesthetic zones had almost vanished.

QUÉNU said that Reynier had stated that the primary suture of nerve-trunks can be followed by immediate restoration of motor function. In the instances upon which he founds his opinion, it is possible that the nerve gives off branches proximal to the point of section, which then vicariously take up the function at once. In his own experiments fifteen years ago upon animals he has again and again obtained primary union of the nerve-ends macroscopically, but upon microscopical examination he found that, however good the union of the fibrous sheaths might be, the axis cylinders were not united, but their ends

rather folded and bent over upon themselves and otherwise deformed. Upon the basis of such observations, frequently repeated he feels sure that Reynier's contention is not founded on fact, but has some explanation like the above of early division.

Poirier argued that Reynier can not possibly have obtained immediate restoration of function beyond the point of division, because this is impossible in the nature of things. Even if it were practicable to place the divided ends of the axis cylinders end to end it would be impossible to avoid the distal degeneration.

Ricard like Quénu had often made observations as to nerve-suture in animals and, although he has often seen the damaged trunks grow together at once, he has never once had any restoration of motor action occur.

Potheral claimed that judicious massage and use of electricity are two therapeutic elements which hasten very materially the return of the nerve activities. In one of his patients eight months after accidental division of the median and cubital nerves, he had obtained decided recovery of function within three and one-half months after suture with primary union, by massage and electricity. In another patient he united the divided nerves within three hours of their separation and under electrical and massage stimulation had seen motor function return in three weeks. They had also absolutely checked any atrophy whatever.

Richelot reported the results of massage upon movable kidneys as advocated by Rosenthal. In a number of patients the pains and many of the other symptoms were seen to disappear. The number of applications varies from twenty to thirty and their effect is sometimes marvelous. The theory of their actions is that the pain and many of the other complaints in the displaced kidney are due to simple congestion inherent in the abnormal circulatory conditions. The massage properly carried out appears to dispel this congestion and therefore to relieve the symptoms more effectually than nephorrhaphy itself does sometimes.

Guillain, at the Société Médicale des Hôpitaux, May 3, 1901, related in the name of Marie and himself an experience with the cephalalgia of chronic Bright's disease of the kidneys. The headache had been chronic and of very long standing and entirely resistant of all known means. Finally arguing that probably the pain might be due to augmented pressure of the cerebrospinal fluid, he made a lumbar puncture and withdrew about six cubic centimeters of fluid under high presssure so that it ran in a veritable jet. Several days have elapsed since this was done and the immediate cessation of pain at the time of the operation had continued so that the patient is much more comfortable than for a long time previously.

Le Gendre stated that he, too, had seen several examples of the alleviation, not only of the headache but also of the myosis and insomnia in uremia due to the withdrawal of cerebrospinal fluid.

Netter noted that the quantity withdrawn was very small and seemed to indicate that the pressure had been very greatly increased. Therefore a greater quantity could have been taken away with advantage. In children sick with meningitis as much as forty or fifty cubic centimeters can be withdrawn. Guillain in reply said that the small quantity of six cubic centimeters was taken only because they felt it was wise to stop the flow then.

Triboulet stated that Metchnikoff has recently shown that intestinal worms may be associated with appendicitis. In the presence of such an appendicitis coexisting with worms, one may ask, Is there not therefore a true and a false appendicitis? In a patient of his own who was finally afflicted with round worms there were all the regular and the classic symptoms of appendicitis, prostration, fever, nausea, vomiting, pain and tenderness at and about McBurney's point. There was also a tendency to a return of the symptoms at her monthly periods.

Pierre-Merklen said that this patient was evidently suffering from a true appendicitis, because she had all of the subjective and objective symptoms with recurrences, especially fever vomiting and focal pain. The dependence of the recurrence upon the menstrual epochs was probably purely accidental by the circulatory activity and congestion. While the worms may have been the pathogenetic factor of the disease, it is highly likely that the appendix remains diseased and is suitable for a removal during an interval.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held at St. Paul, Minn., June 4-7, 1901.

(Continued from page 927.)

General Session.

Third Day—June 6th.

After the acceptance of the report of the Nominating Committee, which presented the names of the officers mentioned last week (see Medical News, page 919) the regular order of business was proceeded with.

Vice in the Philippines.—Miss Susan B. Anthony, the President of the National Woman's Suffrage Association, and the Reverend Anna M. Shaw, of the Executive Board of the Association, were, by special privilege, allowed to address the members of the Association for five minutes, each, on the question of "Moral Conditions in the Philippines." They came from Minneapolis where a convention of the Woman's Suffrage Association was being held. They appealed to the Association to memorialize Congress in order to prevent the existence

of vicious conditions in the Philippines, and preclude the possibility of the importation into the Archipelago of abandoned characters from civilized countries. Their proposal did not, however, reach the stage of a resolution and was not voted upon.

State and County Societies.—Dr. MacCormack of Bowling Green, Kentucky, then presented the following resolution which was adopted:

"*Resolved,* That this Association cordially indorse the plan proposed by the Committee of Reorganization for a uniform system of organization of State and county societies in affiliation with this body and the Secretary is hereby instructed to correspond with the officers of each State society and urge the adoption of such plan in so far as it may be applicable, and that he shall report to the next annual meeting the result of such correspondence."

This involves the reorganization of county and State medical associations on the line of recent work in New York so that membership in a local society includes membership also in the general body.

The Code of Ethics.—Dr. L. Duncan Bulkley, Secretary of the Executive Committee, presented a recommendation that a committee of three be appointed to revise the code of ethics. The question was considered so important that it was proposed to call the roll, in order to prevent any but delegates from voting. It was suggested, however, that the roll call would occupy all the time until adjournment would be necesssary, and so the matter was left over until the next annual session.

Annual Oration on Medicine.—Dr. N. S. Davis, Jr., of Chicago then delivered the annual Oration on Medicine. The subject was "Internal Medicine in the Nineteenth Century." An abstract of the address will be found in the MEDICAL NEWS, June 8th, page 889.

FOURTH DAY—JUNE 7TH.

Original Research Fund.—Dr. L. Duncan Bulkley of New York announced the gift by John D. Rockefeller of a fund of $200,000 for the prosecution of original research in medical science. The distribution of this fund is to be under the direction of Dr. William H. Welch of Johns Hopkins University, who is the Chairman of the Committee on Scientific Research of the American Medical Association.

Oration on State Medicine.—Dr. George M. Kober of Washington, D. C., then delivered the Oration on State Medicine. Its subject was "The Progress and Tendency of Sanitary Science in the Nineteenth Century." An abstract of the address will be found in the MEDICAL NEWS, June 8th, page. 894.

The Army Canteen.—The Committee on National Legislation reported favorably on the resolution for the presentation to Congress of a memorial asking for the restoration of the canteen in the army. This report was adopted unanimously and with great enthusiasm.

Dr. Judson Daland of Philadelphia, was appointed to represent the American Medical Association at the World's Congress on Tuberculosis to be held in London in July.

Reception to New President.—Drs. Marcy and Priestley escorted the new President of the Association, Dr. John A. Wyeth of New York, to the Chair. Dr. Wyeth thanked the Association felicitously for the honor they had conferred on him and expressed the hope that he would greet them all at Saratoga in the midst of a large and enthusiastic meeting of the Association.

The Session then adjourned to meet next year at Saratoga.

SECTION ON SURGERY AND ANATOMY.

THIRD DAY—JUNE 6TH.

Hemostasis in Amputation at the Hip-Joint.—Dr. John A. Wyeth of New York said that his method was first made public in 1890. He now has complete histories of 267 cases, which he presented to the Section under three groups, to-wit: (1) Neoplasms, of which 131 were sarcomata, and 5 epitheliomata. (2) Septic infection, 94 cases, 16 deaths: 17 per cent. mortality. (3) Injuries, 36 cases 23 deaths, mortality 63.9 per cent. This is relatively high, most of the cases dying from shock induced by hemorrhage from the injury, which in most cases was that of car-wheels or similar great weights. In all of these cases he now uses a preliminary venous infusion of hot salt solution and feels that this procedure is of paramount importance, not only in these particular conditions, but in the face of all similar surgical emergencies. Whereas prior to the introduction of his technic the mortality was estimated at 64 per cent., it is now but 19.8 per cent.

Autoplastic Suture in Hernia and Other Ventral Wounds.—Dr. L. L. McArthur of Chicago said that this type of suture had been recommended for certain other operations, but had not to his knowledge been used for hernia. The strips are prepared as follows: On either side of the incision made in the internal oblique, bands which promptly roll up into cords about an eighth of an inch wide are cut from above down. If an ordinary Bassini operation be done, after the replacement of the sack, the wound more closely resembles a shoe just ready to be laced than anything else. To one of the sutures is now tied a bit of slender silk on a needle, and with this armature the autosuture is cast continuously to the outer angle of the wound. At the termination of the last stitch the remaining portion of the band is split. The end which still bears the thread is

threaded once more through the tissue and then the two are tied together. This mode of terminating the auto-stitch is rapid and convenient. In a similar way the external oblique is closed, the skin incision being sutured as one pleases. The length of these ribbons varies from four to six inches. Their tensile strength is 17 to 20 pounds. Being fibrous tissue and elastic, it is not necessary for a continuance of their life that they should have a blood-supply, for they live normally by osmosis. Histology appears to show, after a series of most careful sectional examination in animal tissues and in one case of death in a man where this technic had been used, that there is a definite continuance of the life of the tissue. However this may be, in the seventeen cases in which it has been used there had been no instance of postoperative rise of temperature. If this be shown to be a continuous factor, it will prove that this rise which is so constantly present after closing wounds with the ordinary absorbable suture, is due entirely to the dissemination of their constituents through the system.

Dr. Powers of Denver has used the method and cordially endorsed it. Dr. Eisendrath of Chicago tried it with excellent result in a boy of ten. He does not believe that the fears of its author are grounded, namely, that the muscle is not strong enough to give suitable ribbons in women and children. Dr. Eastman of Indianapolis said that without wishing to pick flaws in a technic which was so new and interesting, he desired to ask two questions: Is it not difficult to get sufficient length of ribbon, and, again, does not the external oblique frequently tear during the manipulation? In closing Dr. McArthur said that he had not encountered these difficulties. In adult men, where alone he recommended the technic, he had had no difficulty in getting sutures six inches long.

A New Method of Skiagraphic Diagnosis for Renal and Ureteral Surgery.—Dr. L. E. Schmidt and Dr. G. Kolischer of Chicago presented this paper. Their efforts had been crowned with success, largely because of the very flexible and absolutely harmless wires of lead and antimony which they had introduced into the ureters. This composition is particularly soft and flexible and casts a beautiful picture in skiagraph. Ureters, which by cicatricial distortion and various forms of dilatation of the pelvis are deflected from their normal course, are accurately shown by this process. In the large dilated pelves of hydronephrosis, for example, the wire seems invariably to follow the wall of the sack in such manner as to give a very fair indication of its size and position.

Prostatotomy vs. Prostatectomy for Prostatic Hypertrophy.—Dr. Ramon Guiteras of New York, passing rapidly over the various measures which are still somewhat in vogue in Europe for the relief of this condition, but which here have been abandoned, said that within the last few years such advances had been made toward perfecting prostatotomy and prostatectomy that no progressive surgeon who aspired to do any genito-urinary work could afford to be unfamiliar with both of them. He advocated what might be called the vesico-rectal method. Two fingers placed in the rectum afford the most certain aid in doing rapid work. In conclusion, he said that, while in general he might be considered to favor prostatectomy, the whole problem was too grave a one upon which to dogmatize. There were many patients whose condition was such as imperatively to contra-indicate the radical operation. There were a large number in whom the distinctly palliative treatment of Bottini was the only justifiable course; the unfortunate delays which as yet are invariable in all prostatic cases create a class of feeble old men on whom no operation is justifiable.

Prostatectomy.—Dr. Eugene Fuller of New York, said that the quasi-moral environment of these cases is the most important factor which the progressive surgeon has to struggle against. In almost every case objection is made to any form of radical operation because of the patient's extreme age. Under proper surgical management, the mortality of prostatectomy is not over 8 per cent. or 10 per cent. The argument in favor of the Bottini is that it is easy of accomplishment; any one with some experience in the manipulation of urethral instruments being able to perform it, while prostatectomy calls not only for a well-trained surgeon, but one especially skilled in this work.

Permanent Catheterization.—Dr. J. R. Eastman of Indianapolis embodied in this paper a report of fifteen cases in which the catheter had been retained for from two to sixty days, with a history of the results obtained. He submitted the following details: (1) The traumatic urethritis was not marked enough to do harm; in the sixty-day case, the catheter was not at any time removed. (2) The catheter best suited for this work is of large size and of soft rubber. (3) Boric-acid solutions are not satisfactory for irrigation, as the crystals tend to occlude the lumen of the tube. (4) The catheter must be introduced just within the bladder. (5) It gives absolute rest to the part—a sovereign aid in treatment.

Fallacies of Treatment in Urethral Diseases.—Dr. Robert H. Greene of New York said that from a series of thirty cases of prostatic hypertrophy which had been subjected to the most careful histological study by Dr. Harlow Brooks and himself, he feels certain that the recent views expressed by Cienkanowski, that the prostatic tumor is of inflammatory origin rather than cystoadenomatic, is correct. If it be eventually shown that gonorrhea has any etiological bearing on this disease of old age, it will awaken broad interest among the young.

Perineal Prostatectomy.—Dr. Parker Syms of New York believes that this will be the operation of the future. He exhibited a very ingenious device consisting of a flexible rubber tube with a bulb at one end. A measured quantity of water dilates this bulb 2½ inches. Collapsed, it is introduced into the bladder through a central perineal incision; it is then filled with water and drawn down by an assistant. This most beautifully, and even in difficult cases, brings the prostate into clear view. He invariably removes the left lobe, then the middle and last the right. At the end of seven days the patients are usually able to sit up. He passes steel sounds every third day for a period which gradually increases. In closing he said that the mortality would be much lower when the profession knows as much about this operation and acts as promptly as it does in appendicitis.

Dr. Robert H. M. Dawbarn of New York, in opening the discussion of this genito-urinary symposium said that he preferred to leave the discussion of the papers to others. He thought the Section would be more interested in seeing a device for bladder drainage than in hearing him talk. It consisted of a douche-bag, some rubber tubing and a T-tube. The principle is that of intermittent siphonage which was applied to dentistry twenty-five years ago by Snow of Buffalo. One of the most unique and ingenious points in the whole apparatus is the establishment of the siphon by the simple casting of a single knot in the drainage tube. The method keeps the bed as dry as the De Pezzer tubes or the Kader method or the plan of Blasucci. Another advantage which it has over the more complicated and somewhat expensive devices is its extreme cheapness. One can easily wash out the thick, stringy muco-pus, slime and calcareous material from these filthy bladders which so often give trouble by other methods. Three distinct things can be accomplished by this ingenious bag. (1) The bladder is continuously drained, the time which the nurse has to give to the apparatus being simply long enough to fill the bag once every six hours; (2) the bladder can be so painlessly washed out that it has repeatedly been done without awakening the patient; (3) by interposing a flask in the tube leading from the bladder absolutely uncontaminated specimens of urine can be obtained for examination.

Dr. Rokey of Portland, Oregon said, that not enough attention has as yet been devoted to the prostate. Why is it that while indefatigable researches have been made in the diseases of women, many of which have terminated in a happy liberation of the young and the old from previously hopeless conditions, old men should be left neglected to die a hopeless and horrible death? He prefers the recto-vesical technic and his mode of procedure is practically analogous to that of Guiteras.

Dr. Andrews of Chicago indorsed the auto-suture saying that its chief characteristic was the absence of post-operative temperature. Prostatectomy in the mid-perinum is the operation of the future. While he regards Syms' apparatus as of great value, he believes that Ferguson's prostatic retractor is perhaps in some respects better. It is a sort of spoon, about No. 25 French in size. It is inserted via the penile urethra, rotated through 180 degrees, and is then thrown up against the pubes. This at once accomplished two things, i. e., it drags the prostate into view and, by putting considerable tension on the tissue, avoids hemorrhage.

Dr. McGowan of Los Angeles believes that Dr. Greene's evidence is of very little value. The hypertrophic prostate is not of inflammatory origin.

Dr. Guiteras in closing said we shall soon, it is hoped, have not only a good technic, but an interest awakened in this important work which will lead to a recognition of the fact that early operation and radical operation is as much to be desired in these cases as it is in appendicitis.

Dr. Fuller in closing said that the Chinese and Asiatics in general are exempt from prostatic hypertrophy, although it is well known that probably more than all other nations they suffer from venereal disease. The bladder does regain tone and there is hope in the majority of these cases.

Dr. Greene said that he did not expect his theory to be accepted without marked opposition. If correct, however, it would effect very great changes in the treatment of urethritis, and probably develop a new and perhaps less radical operation than prostatectomy.

Pneumectomy and Pneumotomy.—Dr. J. B. Murphy of Chicago defined chest surgery as an opening of the mediastinal or pleural cavities. Until the present time but little progress has been made in the surgery of the chest, because of the extraordinary dangers which have attended all work in this region. The dangers he classifies as follows: (1) Primary pneumothorax, (2) primary hemorrhage, (3) secondary pneumothorax, (4) sepsis. The effects arising in primary pneumothorax are probably absolutely mechanical. We must remember that the mediastinal septum is not a solid body and that with a decrease of the atmospheric pressure on the uninjured side there will naturally be a bulging from the injured area. How this can best be overcome is probably answered by the immobilization of the mediastinum by clamps on the hilum of the lung which can thus be retracted, or by insufflation. In perfecting their insufflation apparatus, Matas and Parham have done a vast work for the surgery of the chest. The next difficulty to be encountered and overcome is hemorrhage. Of special danger is the hemorrhage from the internal mammary ar-

tery which gives a more rapid flow than any other vessel of the third magnitude. There are three important dangers from hemorrhage from the tissue of the lungs as follows: (1), if the azygos vein be torn, air embolism is probable; (2) the subclavian, but this occurs only in apical tuberculosis; (3) rupture of the right auricle in kindred conditions where it is known often to be adherent to the lungs. Secondary pneumothorax resulting either from a re-opening of the cut or a dividing of a bronchus is best overcome, together with the hemorrhage, by the angiotribe. The closure of large bronchi is most difficult, although it is to be believed that here again this instrument will come to our help. The sepsis arises from two sources. It may be primary-induced at the time of the operation, as in any other wound. It may at this time be caused by the breaking of a focus of pus. It may arise secondarily from infected bronchi.

Foreign Bodies in the Trachea and Bronchi.—Dr. De Forest Willard of Philadelphia said that for removal of foreign bodies from the air passages inversion of the child and succussion are dangerous unless the means for immediate opening of the trachea are at hand, as lodgment in the larynx may quickly suffocate the patient. A careful physical examination, with study of all the symptoms, is absolutely essential to determine their location and the lung condition. A low tracheotomy should be at once performed, a large opening made, the sides of the slit being kept wide apart by silk stitches. Through this opening expulsion is common and is ordinarily to be expected. If the object cannot be secured through the trachea, an opening into the chest and incision of the bronchi themselves is only justifiable when an artificial apparatus, like the Fell-O'Dwyer, is at hand, and oxygen is available. Without these accessories, combined with the skill of a cool, cautious operator, the search for a foreign body through the chest walls is attended with such dangers that it is ordinarily unjustifiable. Since the introduction of the Parham-Matas instrument many of the dangers of lung surgery have been removed.

Treatment of Empyema.—Dr. J. H. Dunn of Minneapolis said that early in the disease, except in the case of certain contra-indications, one or more should be exsected, but there is little use of doing this unless a large opening is made. At least 2½ inches of bone should be removed. Immediate irrigation is to be deprecated. Simple drainage and wiping out is sufficient. Probaby there are no indications for irrigation at the time of the operation and it is very doubtful if at any time these exist. To hold the passage patent a light gauze packing is found to be much better than a rubber tube, which is not only apt to drop in or out, but sometimes provokes the formation of a fistulous opening which is difficult to close. In these cases subsequent infection should be most scrupulously guarded against. Estlander's operation is giving place to Schede's in which the greater part of the chest-wall is removed and the skin allowed to fall in upon the retracted lung.

In the discussion of these papers, Dr. Bernays of St. Louis said that he hoped the time was not far distant when the surgeon would have the care of a great many cases of pulmonary tuberculosis which now fall to the general practitioner. They will naturally be those in which a mixed infection has occurred.

Dr. Dunn's observations as to the value of bacteriological examination of all pleural fluids is very important. He agrees that irrigation is ill-advised here as elsewhere, and believes free drainage to be all requisite.

Dr. Barbat of California said that he had had some success with lung surgery for which he had devised an insufflator similar to Parham's. He passes the air, however, through hot water which not alone elevates its temperature and moistens it, but renders it sterile as well.

Dr. Wills of Los Angeles said that none of the Eastern members had one-half the interest in lung surgery that is felt by the surgeons of the Pacific coast. It is time that some active steps were taken to stop the alarming influx of hopeless tuberculous patients in regions where, at least until recently, the tubercle germ was practically unknown. If they must be sent from the East, let it be before they are in a hopeless condition.

Dr. W. W. Keen of Philadelphia finds that a pair of curved Hagedorn needles passed in through a part of the lung and out again accomplishes the formation of sufficiently dense adhesions within twenty-four hours. In a case of sarcoma of the chest-wall he had successfully resorted to the expedient of sewing the lung fast all around the large thoracic opening to prevent primary pneumothorax.

Dr. Means of Columbus, Ohio, cited two cases of thoracic surgery. In one of them, a shot-gun wound, the pleural cavity was filled with a mixture of clothing and newspaper. After hearing what Dr. Murphy had said regarding the deviation of the mediastinal septum and its mode of prevention, he thought that this very fact which he had believed would be fatal, had by steadying the septum actually preserved the patient's life.

In closing the discussion, Dr. Willard spoke of secondary emphysema which is pretty sure to develop in the event of failure to close a bronchus. This can usually be successfully accomplished with a fine staphylorrhaphy needle. This emphysema is progressive and may cause death. Because of the possibility of this complication it is probably better to drain than to close. Adhesions should always be produced prior to opening a cavity which would otherwise communicate with the pleural cavity.

FOURTH DAY—JUNE 7TH.

Indications for Operation in Calculus, Nephritis and Ureteritis.—Dr. C. L. Leonard of Philadelphia said that within a very recent time the X-ray has shown the unsuspected relative frequency of ureteral calculi. It has also demonstrated that the writer has an extraordinary tolerance for these concretions. They appear in many cases to dwell within the lumen for years without causing an ache or a pain. Now that we have a means of keeping the stones under immediate and accurate observation, fewer exploratory incisions will be necessary. That this method is a sure one has been shown by observation on 165 cases where the prognosis made by the X-ray was either correct or was shown to be faulty because of defective technic. This has been a means of vastly improving it. Over 50 per cent. of the calculi have been found to be in the ureters. The urine, which till now has always been thought to be of paramount import, has been shown to have a very variable value. A large kidney is usually looked upon, in the absence, of course of neoplasm, as a favorable sign and one contra-indicating operating for a ureteral stone, for it has the energy to drive the stone before its larger volume of urine. A small kidney, on the other hand, is in a measure an evil omen, for with no *vis a tergo* to dislodge it the calculus will very likely have to be removed. It is of particular import that efforts be made to clear the urine of as much pus as possible prior to operating. Multiple calculi do not always indicate operation. Inter-ureteral operations have been much advanced by the X-ray and they are perhaps best practised by a special technic through a primary suprapubic cystotomy. Finally, from the great class of cases where conservatism is the best treatment, the X-ray has given us a certain method of separating those in which immediate operation is indicated.

Acute Infection Cholangitis and Cholecystitis as a Complication of Gall-Stones.—Dr. D. N. Eisendrath of Chicago read this paper. In the normal state, the ducts, beyond the ampulla of Vater are sterile. Probably the bile inhibits the growth of the colon and typhoid bacilli. Infection is probably the causation factor in stone formation. The effect on the hepatic cells is to inhibit their normal bactericidal power.

Dissecting Abscess of Abdominal Wall.—Dr. J. B. Bullitt of Louisville, Ky., reported at length a case in which six weeks after the subsidance of typhoid fever there developed a rapidly spreading abscess which proved to be the abdominal wall.

In the discussion, Dr. Smythe of Memphis reported a case which illustrated the extent and fatality of gonorrheal infection. To a surgeon of the Southern Mississippi Valley, the discussion on gall-stones had been particularly interesting. Jaundice seems but rarely to be associated with gall-stones. He always irrigates the bladder with silver nitrate after removal of stones and, if the walls are not too diseased, he closes it by a special technic.

Dr. McGowan of Los Angeles asked Dr. Leonard how positive he could be in diagnosing renal calculi with the X-ray. He cited two cases of so-called burns which had been under his care. In each he was obliged before any progress began, to excise the poisoned tissue just as thoroughly as though it had been neoplastic. One healed in a year, the other in eighteen months.

Dr. Crane of Vermont said that the depth of the shadow is dependent on the atomic weight. Uric-acid stones, for example, do not weigh as much as those of calcium oxalate and the shadows vary resultingly.

Dr. Davis of Omaha has experimented to find the nature of the nucleus of gall-stones. His findings lead him to corroborate the statement that their nuclei are almost always clumps of germs. He protested against the closure of the bladder; it should always be drained till all signs of infection have passed away.

Dr. Dunsmore of Minneapolis wished to emphasize the importance of "clinical sense." He thinks the gall-bladder can often be closed to advantage.

Dr. Rodman of Philadelphia said that in his city the X-ray had been so perfected that its findings were now considered more reliable than the "clinical sense" of anybody. Burns no longer occur in the practice of experienced operators. This is true even when the X-ray is used on the face and the eye.

Dr. Lemon of Milwaukee said that the question of dissecting abscesses of the abdomen after typhoid was important for he believed them to be more frequent than the literature would seem to show. In his own experience were two cases.

Dr. Bloodgood of Baltimore spoke of the relation of gall-stones to pancreatitis. Opie has shown that the anatomy of the pancreatic and biliary ducts and their relation to each other and to the duodenum is a very important factor in the etiology of both these diseases. It teaches a very important lesson as to the desirability of always draining the gall-bladder rather than closing it. If a small stone partially obstructs the papilla of Vater, some bile will be forced into the pancreas. Since the papillary mucous membrane is normally septic, this bile is infected. We then have those conditions present which are known to produce acute hemorrhagic pancreatis, blocked ducts and infection.

Dr. Porter of Fort Wayne believes that the colic is not produced by the passage of stones, as is usually supposed. The pain and the jaundice are both due to infection and inflammation.

Dr. Leonard in closing said that he wished to impress on the Section the fact that the X-ray, with its power of positive diagnosis, has introduced into the surgery of renal stones a conservative element which would and could not otherwise exist. His experience leads him to believe that burns, so-called, are not produced by the ray, but by an unknown factor. He has had two severe burns himself and yet he rarely if ever puts his hand in the line of the ray. Whatever it is that does the burning seems, in his case at least, to have been around the tube. A grounded screen has afforded him protection of late.

Dr. Eisendrath in closing said that Mijake, a Japanese investigator, has shown by a series of experiments on dogs that neither infection alone nor obstruction alone will cause the development of stone, but in the presence of each calculi are almost certain to form.

Dr. Thompson of Scranton, Pa., showed the head and part of the shaft of the femur of a man, aged sixty-two years, on whom he had performed Gillette's operation for non-union. Making a bone-flap, which consisted of the great trochanter and a part of the shaft, he drove a solid-silver nail directly toward and to the head of the bone. A smaller nail held the flap in place; the wound was closed and a plaster spica applied from axilla to toes. In six weeks the man walked without a limp.

A Simple Operation for the Treatment of Hemorrhoids.—Dr. J. R. Pennington of Chicago read this paper. These tumors are simply angiomata. The indication is to remove them *in toto* with the least possible destruction of normal tissue. He slits the mucous membrane over each tumor, enucleates and excises it. A stream of salt solution courses over the site of the operation while this is being done. These cases recover in an unusually short time; in four to five days they are usually out of bed and at work.

Section on Practice of Medicine.

Third Day—June 6th.

Modified Typhoid Treatment.—Dr. T. B. Greenley of Meadow Lawn, Ky., said that little drug treatment is needed in typhoid fever. He has used the Woodbridge method of treatment, but does not believe in its efficacy. The drugs he has found most satisfactory are quinine and acetanilid. He employs one grain of each every three of four hours. In severe cases every two hours or even every hour. Baths or spongings should be directed. Turpentine is the best remedy for tympanites. In fact, in Dr. Greenley's experience, it is almost a specific. Turpentine is an excellent prophylactic against hemorrhage. This is true, not only in the severe hemorrhage of the third week, but also in the hemorrhages from the nose in the early stages, if these are giving inconvenience. Under these remedies typhoid fever has decreased in fatality. The disease has lost most of its terrors even in conditions where good nursing is hard to obtain, though of course nursing is the most important element in the care of these cases.

Medical Shock.—Dr. O. T. Osborne of New Haven, Conn., read a paper on this subject. He said that the term heart failure has fallen into disrepute. It is true that in many cases the term was used to cover the ignorance or carelessness of physicians. There is, however, a set of symptoms often serious, sometimes fatal, with failing heart as a prominent symptom, in which no sufficient organic lesion can be found to account for the patient's condition. These symptoms are not unlike those which develop in what is known as surgical shock. The underlying basis of the condition is evidently a disturbance of the vasomotor mechanism that allows diversion of the blood into paralytically dilated veins and so permits reduction of blood-pressure. We need a term for these conditions when no direct cause can be pointed out in some definite organic change.

Definition of Medical Shock.—Dr. Osborne proposes to call all cases medical shock in which the prominent symptom is a failing heart without any change of the muscular apparatus or valvular mechanism to account for the failure. That such cases occur, every practitioner knows. The main symptoms are a rapid, excited heart, with decreasing energy, great loss of heat from dilatation of the peripheral vessels as the result of paralysis of the vasomotors, weakness and faintness, with pallor because the blood is mainly contained in the large abdominal veins. Blood-pressure is so much reduced that the heart-muscle itself suffers in its nutrition because of defective circulation.

Analogies with Surgical Shock.—In surgical shock the symptoms are prone to develop after injuries to special parts—the head, the abdomen, the testicles, important nerves and the like. Medical shock is apt especially to develop during affections of these same parts. Pain is an important causal factor in the production of surgical shock. It seems to be also in the production of medical shock. This pain need not necessarily be very severe. In weak patients even slight pain may cause serious reflex symptoms. The more or less imaginary pains that hysterical or neurasthenic patients suffer from may well produce as much medical shock as if they really suffered all the pain they imagine. Pain reflexly produces vasomotor paralysis and consequent reduction of blood-pressure. This soon adds to the heart weakness.

Medical Shock in Typhoid.—This condition of progressively failing circulation is often seen in typhoid fever. The heart is weakened

by the toxins of the disease. The irritation of the intestinal mucous membrane causes active and passive congestion in the abdomen that still further disturbs the circulation. If tympanites comes on to add a mechanical factor of interference with the circulation, heart and vessels, it can be readily imagined that symptoms of failing heart may develop.

Treatment of Medical Shock.—This must be like that of surgical shock. As absorption from the stomach is interfered with by the failure of the circulation, the drugs indicated must be given hypodermically. Strong stimulants must be employed and they should be administered in full doses. Absorption even from the subcutaneous tissue is slow. This accounts to a large extent for the tolerance for large doses of drugs of patients suffering from such conditions as delirium tremens. Medical shock and heart failure are practically convertible terms, but we seem to have in the analogy with surgical shock some rational basis for the introduction of the new term.

Multiplication of Terms.—Dr. Lillie of St. Louis said that the new term seems to add nothing to our realization of the conditions that exist. The word shock should not be used unless some suddenly developed condition is implied. The introduction of the new term seems scarcely justified since it would only lead to needless multiplication of terms.

Medical Shock Clinically.—Dr. James J. Walsh of New York said that the term medical shock would be helpful to the practitioner and student of medicine, because it assumed the existence of a medical condition analogous to surgical shock, that is, a failure of function without pathologic lesion to account for it. Since heart failure has been tabooed by boards of health there has occasionally been felt the need of a term to describe certain cases of failure of circulation without serious organic involvement. Dr. Osborne's term is illuminative, too, since it suggests the need for prompt and effective medication. Sometimes these cases are allowed to proceed without any realization of how suddenly they may become serious and even fatal. The necessity for hypodermic medication is an important practical point, for at times, though sufficient stimulant drugs have been given they have failed of absorption and the condition continues to grow worse.

Abuse of Heart Stimulants.—Dr. Kelsey of Minneapolis said that sometimes, when it is known that patients will eventually need heart stimulants, the administration of these remedies is begun early in the disease. Of course, it is always a serious question in infectious and especially exhausting diseases to know when to begin the employment of stimulant medication. Probably more harm than good is done, however, by beginning before there is some absolute indication for them. Their use by anticipation of symptoms only serves to make the individual accustomed to their action and so detracts from their effect when they are really needed. This mistake is often made and with the best intentions in the world. Dr. Kelsey detailed a recent case in which heart stimulants failed to produce the desired effect and the reason seems to have been their persistent use in the case for some time before the development of any critical symptoms.

Weak Heart without Lesions.—Dr. Webster of Chicago said that there is often a condition of weakness of heart without distinct lesions. The valvular apparatus is unaffected and the muscle seems healthy, yet the heart acts poorly. Often this is due to toxic conditions and the resulting failure of nutrition. In these weakened states reflex nervous inhibition is especially active. Dr. Webster once saw a rabbit about to be experimented on die from sheer fright. The animal was literally scared to death. The heart was found contracted and practically without blood. The large abdominal veins were found widely distended and filled to repletion with blood. The animal had bled to death into its own abdominal veins. This condition is not impossible in human beings. It is due to disturbance of the vasomotor functions and consequent paralytic venous distention. That it is analogous to shock under some circumstances cannot be denied.

Spread of Tuberculosis.—Dr. E. Napoleon Boston of Philadelphia read a paper discussing the spread of tuberculosis because coughing caused a disseminating of tubercle bacilli through the air. This is perhaps not so dangerous as has been thought, but is certainly an important method for the spread of virulent infectious material. Experiments have shown that the dust of sanatoria for consumption does not always contain tubercle bacilli and that those found are often inactive. Flügge does not think that dried sputum of tuberculous patients is virulently contagious. The bacilli do not long withstand drying. The bacilli contained in recent moist sputum are virulent and those on the minute droplets of sputum ejected during coughing or sneezing or even talking may convey the infection.

Experimental Investigation.—Solution of cultures of Bacillus prodigiosus have been placed in the mouths of patients and after some time cultures of this microbe could readily be obtained in the room. Curry found that when a plate was placed six inches away from tuberculous patients it almost invariably became infected during coughing spells. A single exposure of the plate was sufficient to infect it in the early morning hours. Many more colonies were found in plates exposed in the mornings than in the evenings. Ravenel showed that tubercle bacilli were deposited on all of a series of pieces of wood placed in the bottom of a nose-bag used by tuberculous cattle. These cattle were not severely infected, for one of them was alive two years later.

Danger from Food.—There is no doubt that coughing in a refectory will easily and frequently lead to the deposition of tubercle bacilli on food. Dr. Baston has demonstrated this by employing a mask. This is worn only for an hour a day and that hour the one in which least coughing occurs in each individual case. Despite this precaution the plate is found to have tubercle bacilli deposited on it. In some cases the bacilli are on the droplets of sputum; in others in the thin film spread over the plate.

Protective Influences.—Talking above a whisper always leads to the ejection of bacilli. Whispering does, however, not cause bacilli to be given off. Men with mustaches were found not to give off bacilli. When, following a suggestion of Dr. J. Solis Cohen of Philadelphia the mustaches were waxed, there was no difficulty in demonstrating the exhalation of bacilli. These observations especially serve to show how few protective precautions would be needed to prevent the spread of bacilli broadcast as at present.

Practical Applications.—Dr. Boston is of the opinion that this method of collecting and examining bacteriologically the atomized exhalations from the mouth may be of assistance in the diagnosis of tuberculosis in cases where the sputum can not be obtained. In insane patients, for instance, who refuse to allow the collection of sputum, a culture plate might easily be placed near them. In children in whom tuberculosis of the lungs is suspected at an age before expectoration has begun, the placing of a culture plate before the mouth during an attack of crying may easily lead to the detection of the bacilli if they are present in the mouth secretion.

Prophylaxis in Other Diseases.—It must be remembered that the atomized secretions of the mouth may easily convey other diseases besides tuberculosis. There is no doubt, for instance, that in diphtheria the Klebs-Loeffler bacilli may be ejected from the mouth, just as the tubercle bacilli in tuberculosis. In cases of tonsillitis that are non-diphtheritic, streptococci and other pyogenic cocci may be scattered about. We do not as yet know the germ of scarlatina, but there seems no doubt that an active focus of the microbe occurs in the throat and that it too may be scattered abroad by coughing or talking. Surgeons who have any infective process in their throats may easily introduce infective material into a wound during the course of an operation. Fortunately most of the bacteria contained in the mouth in health are not infectious. The use of a gauze mask is, however, an excellent precaution and it would undoubtedly lower the number of infections that take place during operation, most of which come from some utterly unexplained source.

Diphtheritic Cultures from Throats.—Dr. M. H. Fussell of Philadelphia contributed a paper on the "Practical Value of Cultures From the Throat" which was read by Dr. Webster of Chicago. Dr. Fussell said that for the purposes of therapeutics and prophylaxis of other people, prompt diagnosis is needed in no disease more than in diphtheria. The early administration of diphtheria antitoxin practically assures a cure. Early segregation means the prevention of the spread of the disease. We now know that the Klebs-Loeffler bacillus is pathogenic for diphtheria. We know too that there are a number of exudates that occur in the throat which are due to some other microbe than the Klebs-Loeffler bacillus and that diphtheria may occur in regions apart from the throat and that the diphtheria bacilli may produce constitutional symptoms without throat exudate. In a word, we are unable to decide clinically on the existence, or non-existence of diphtheria, and must depend on the bacteriological test.

Differential Diagnosis.—Baginsky of Berlin first claimed that diphtheria could be diagnosed with absolute certainty only by taking cultures from the throat. His opinion in this matter met with a good deal of opposition at first. There is no doubt, however, that exudates having all the clinical characteristics of true diphtheria pseudo-membrane may occur in the throat without the presence of diphtheria bacilli as a causative agent. On the other hand, no clinical description can be given that will enable the practitioner to pick out the cases that are not diphtheria from those which are virulently diphtheritic. Our only resort, therefore, is the bacteriological diagnosis.

Latent Diphtheria.—Many years ago Jacobi of New York, with wonderful acuity considering the conditions of our knowledge at the time, declared that more diphtheria was walking the streets than was confined to beds. There is no doubt that very many cases of sore throat for which patients receive very little treatment are really due to diphtheria. It is the presence of these cases in a community that keeps the disease alive and continues to spread it. As a rule, physicians do not care to even hint at diphtheria unless there is a severe illness. Hence the question of taking cultures from the throat in all cases of sore throat meets with no little opposition from doctors. In Dr. Fussell's own district the practice of taking cultures has been discontinued to a large extent, because doctors do not wish to inconvenience themselves nor to put their patients to the inconvenience of confinement to their houses until diphtheria bacilli have disappeared. However, there is absolutely no other way of protecting the community.

Patients' Own Benefit.—Besides benefiting others, patients themselves are benefited by the practice of taking cultures. True diphtheria may begin with very few symptoms, be clinically unrecognizable for several days and

then light up with a virulence that makes it fatal almost before anything can be done. On the other hand, tonsillitis may be very severe, simulate diphtheria very closely, give the family great uneasiness, and yet prove to be non-diphtheritic. Even mild diphtheria should be treated at once by diphtheria antitoxin. Severe tonsillitis, non-diphtheritic in character, will not receive the slightest benefit from the antitoxin.

Supposed Pathognomonic Signs.—It has been claimed at times that the diagnosis of diphtheria could be made from the character of the exudate in the throat. It is sometimes said, for instance, that non-diphtheritic membrane can be detached from the mucous membrane without leaving a bleeding surface underneath it. In diphtheria the exudate is hard to remove and always leaves an ulcerative bleeding patch. Dr. Fussell detailed some cases in which these supposed pathognomonic symptoms proved misleading. Particularly is it true that non-diphtheritic exudate may cling very pertinaciously and leave a small ulcer when detached. Dr. Fussell suggests that each physician should have a small laboratory of his own at home in which these cultures can be made, unless the Board of Health of his district will do the work for him.

Persistence of Diphtheria Bacilli.—Dr. Delancey Rochester of Buffalo said that it was surprising how persistently the diphtheria bacilli cling to the throat, after they have once secured lodging there. As long as the diphtheria bacilli remain there is danger of spreading the disease. Patients should not be permitted to associate with other people merely because they have no clinical symptoms, unless it can be shown that there are no diphtheria bacilli in their throats. To demonstrate this the taking of cultures is absolutely indispensable. For the removal of bacilli from the throat, Dr. Rochester used to employ Loeffler's solution. Little patients objected to it so much that he used it on his own throat and found it extremely painful. Since then he has not employed it.

Nitrate of Silver Applications.—Dr. Rochester has found the application of a solution of nitrate of silver, stronger according to the age of the child and its insensitiveness, an effective measure for the early removal of bacilli from the throat. As is well known, nitrate of silver produces very little inconvenience. This is applied once a day for some days and a reduced solution of hydrogen dioxide is directed to be used every three hours. This method of treatment soon disposes of bacilli that may happen to be present in the throat.

Milk and the Spread of Diphtheria.—Dr. Newton of New Jersey said that in a recent epidemic of diphtheria all the cases occurred in families who were taking milk from one dairy. The health inspector made an investigation at the dairy and found that two of the employees, who had suffered a short time before with some slight clinical symptoms of throat trouble, still harbored bacilli in their throats. He even found the probable source of this diphtheria was the handling by these men of bottles collected from infected cases. These bottles were not washed at once, but were allowed to collect for some time, until a sufficient number was obtained to make their cleansing by steam more inexpensive than if each group of bottles were disinfected when collected.

Precautions Taken.—As soon as the dairy was closed no new cases of diphtheria occurred. The habit of collecting bottles from houses infected by diphtheria, or any other contagious disease was forbidden. Beyond this it was required that whenever throat symptoms, no matter how simple in character, developed in any of the employees, the individual should not be allowed to handle the milk, unless after bacteriological examination it should be determined that the throat affection was simple and non-contagious. It seems probable that a good many more epidemics are spread by neglect in dairies than is usually thought. We have come to realize in recent years that typhoid fever and scarlet fever, as well as diphtheria, are apt to follow certain lines of milk distribution. The employment of proper precautions will prevent this.

Cold and Bacteria.—Dr. Newton said that this epidemic of diphtheria would probably have been much more widespread and virulent, but for the fact that all the milk collected at this dairy is cooled to 40° F. as soon as possible after collection. At a temperature of 40° F. very few bacteria propagate. Diphtheria bacilli fail to grow almost completely. The fact that some cases of the disease occurred, shows that all reproduction is not prevented. It is possible that the reproduction took place even during the short time after milking, before the milk was put on ice. Where this precaution of cooling the milk almost at once is not taken there is great danger of wide distribution of infectious material.

Public Prophylaxis.—Dr. Little of St. Louis said that public prophylaxis of disease should be the watchword of the medical profession of the present day. It requires special effort, but this effort is well rewarded. Unfortunately, our boards of health are too often in the hands of politicians and political influence is brought to bear to prevent the impartial working of the law. The medical profession must rise above these untoward influences, and we must use the means that bacteriology has given us for the prevention of disease. The bacteriology of diphtheria is the most helpful contribution to medicine that the related science has brought us. By learning its practical application we will probably be able early in the present century to do away with most of the epidemic diseases.

Genito-Urinary Examinations.—Dr. Ferdinand C. Valentine of New York read a paper on genito-urinary examinations, as they can be made by the general practitioner. This he illustrated by a series of demonstrations on selected patients. He said that most of the genito-urinary examinations are entirely within the scope of the general practitioner's work. Only exceptionally is a trained urologist needed. Dr. Valentine then proceeded to show what he considered the essentials of a genito-urinary examination.

Symposium on Pericarditis.—Dr. Frank Billings of Chicago detailed a series of cases in which the diagnosis of pericarditis was made only postmortem. These cases illustrate the difficulty of diagnosing the condition and the possibility of its escaping notice even where careful methods of diagnosis are in vogue. In one case the patient was suffering from emaciation when admitted, was feverish and breathing very rapidly. The pulse was 120 and weak and irregular. As the patient remained in the hospital, the breathing became shallower and faster. The heart area was overlaid by emphysematous lungs, so that the usual heart dulness was obscured. This took away the principal physical sign of pericarditis.

Etiology.—This patient suffered also from some swelling of the wrists and ankles that seemed to be purulent in character. The removal of fluid from one of the joints showed the presence of biscuit-shaped diplococcus and some staphylococci. The patient was also suffering from a slight urethral discharge in which gonococci were found in the form resembling the biscuit-shaped diplococci of the joints. The temperature became remittant, rising as high as 104.4° F. in the evening. The patient gradually grew weaker with a pulse at 140 and the respiration at fifty-six.

Ante- and Postmortem Diagnosis.—The antemortem diagnosis had been septicopyemia, complicated by endocarditis with the arthritic involvement probable as gonorrheal complications. At the autopsy there was found, in addition to this, a sero-fibrinous pericarditis with a large amount of fluid in the pericardial sac.

Pleurisy and Pericarditis.—In another case the symptoms of pleurisy were detected on the left side, pulsus paradoxus developed and the patient became so uncomfortable that the pleuritic effusion was drawn off. A considerable amount of discolored fluid was withdrawn from the pleural cavity, containing an almost pure culture of the colon bacillus. The fluid reaccumulated several times and was withdrawn, each time becoming clearer in color and also sterile, the bacillus coli communis having disappeared. Notwithstanding the withdrawal of the fluid from the pleural cavity, the patient continued to grow worse and finally died. At the autopsy the pericardial sac contained a large amount of clear fluid.

Pathonomonic Symptoms of Pericarditis.—Dr. Billings said that there are no genuinely pathognomonic signs of pericarditis. The most significant physical signs are the extension of the dulness far to the left and to the right and the fact that the apex beat is distant from the left border of heart dulness as it can be demonstrated.

Pathology of Pericarditis.—Dr. Joseph McFarland of Philadelphia discussed this subject. He said that at the origin of medicine, heart disease was supposed to be incompatible with life. The heart as the origin of life and its disease were supposed to be instantly mortal. Galen noted the existence of pericarditis in animals and inferred its occurrence in man. Some of the old chroniclers referred to the hairy hearts of heroes, and it seems not improbable that the reference is to the stringy fibrin that would be found in the case of old fibrinous pericarditis.

Occurrence of Pericarditis.—The disease occurs at all ages though more frequently in adult life and attacks males more than females. Barthez and Riet found the proportion in a series of cases 21 males to 3 females. Bamberger found 33 males to 25 females. Simpson found 35 males to 28 females. All conclusions favor the preponderance of the disease in males, probably because they are more liable to the exposure and accidents which lead up to the disease.

Pericarditis, Primary and Secondary.—Primary or idiopathic pericarditis is still supposed to exist. The name is retained for such cases of infection of the pericardium that occur through a lesion which can not be found. As a rule, pericarditis is secondary and occurs as the result of the metastasis of infective agents. These agents may come either through the blood or the lymph.

Lymphatogenous Pericarditis.—This form of the disease occurs as the result of the extension of an inflammatory process from some neighboring focus or from trauma in the vicinity or as the result of foreign bodies in the stomach or esophagus or by the burrowing of an abscess from the lungs, or as the result of the pressure or rupture of an aneurism of the aorta. Or it may occur exceptionally by the burrowing of infectious agents from the skin surface in the precordial region.

Hematogenous Pericarditis.—This may occur in the course of any infectious fever. It is especially liable to occur in rheumatism or in scarlet fever. The proportion of cases in rheumatism in which pericarditis occurs varies very much according to different authorities. One French authority states that as high as 85 per cent. of cases of rheumatism are complicated by pericarditis. Bamberger found that about 30 per cent. of cases of rheumatism under his observation developed some symptoms

of pericarditis. One observer has found as low as 5 per cent. of rheumatic pericarditis. It occasionally occurs during gonorrheal rheumatism, and develops more frequently in the course of polyarticular than in monoarticular rheumatism.

Rheumatic Pericarditis.—Dr. MacFarland said that it should be borne in mind that the cause of rheumatism has especial affinity for the inner and outer linings of the heart. Pericarditis for instance may occur before there are any rheumatic symptoms in the joints. Rheumatic pericarditis may develop and run its course without any symptoms of rheumatic arthritis accompanying or even following it. In these cases, of course, the diagnosis may easily be missed and the occurrence of fever without good cause should lead to the careful examination of the heart region.

Scorbutic Pericarditis.—Scurvy may cause hemorrhages into serous cavities and these are liable to become infected. The pericardial sac is no exception to this rule and scurvy is a very prominent cause of pericarditis. It leads to the effusion of a sero-sanguinal fluid within the pericardium. Scurvy may become endemic and practically every case of the disease may be complicated by pericarditis. This set of symptoms would seem to constitute the morbus cardiacus of the older writers.

Pericarditis in Chronic Nephritis.—Chronic kidney disease is very frequently complicated by pericarditis. The reason would seem to be that the deterioration of eliminative processes causes distinct lowering of the resistive vitality. When chronic nephritis gives rise to generalized dropsy there is always an effusion of serum into the pericardial sac. This is not merely a mechanical transudation, but is due also to the fact that the retention of toxic materials in the circulation renders the vascular walls less retentive of the blood serum.

Pericarditis and Microbes.—There is no specific microbe for pericarditis and many forms of micro-organisms enter into its causation. The pneumococcus and Friedlander's bacillus are very prominent factors in etiology and may give rise only to serous effusion. In purulent pericarditis any of the pyogenic cocci may be found, or the pneumococcus or Friedlander's, or the bacillus coli communis. When the fluid within the pericardial sac is hemorrhagic in character, the causes of pericarditis will usually be found to be the tubercle bacillus. Unless, of course, some recent trauma serves to account for the presence of the blood, in the serous effusion.

(To be continued.)

AMERICAN ACADEMY OF MEDICINE.

Twenty-Sixth Annual Meeting, Held at St. Paul, Minn., June 1 and 3, 1901.

A REGISTRATION of 50 and an addition of 48 members represents the cold facts concerning the twenty-sixth annual meeting of the American Academy of Medicine. It thus begins its second quarter of a century under auspicious circumstances. The simple tabulation of statistics, however, does not give the true value of the meeting.

The subjects under discussion consisted first of a Symposium on "Reciprocity in Medical Licensure," in which the trend of thought seemed to be away from pure reciprocity toward a conditional examination of those men moving from one State to another who had already acquired a license to practise by an examination before a State board. It was thought, on the one hand, that it would be almost impossible to so synchronize the movements of the various State boards of medical examiners as to make the examinations practically equivalent; and, on the other, that certain fitness to practise shown by those who had already been in practice should be accepted in lieu of an examination upon the primary subjects, while certain other tests should be applied which could easily be met by any one engaged in active practice if he were at all fit to receive a license.

The other symposium was entitled "Institutionalism," but the papers rather treated of its abuses. They were all suggestive and will form an interesting contribution to the subject. Special mention should be made of a paper by Dr. Hill of Iowa upon the present method of supervising institutions of that State, whereby a commission of three, giving their whole time and receiving a salary from the State, supervise the management of all institutions for defectives. It removes the oversight of these institutions from politics and is working very well.

Another paper by Dr. H. Bert Ellis of Los Angeles describes a hospital in that city owned and controlled by medical men for profit, not philanthropy, which serves as a fair investment for the money and is a great convenience to the profession in that city.

In addition to the papers connected with these symposia were several of great interest, Dr. Cattell of Philadelphia giving the details of the executive management of clinical laboratories in connection with hospitals; Dr. T. D. Davis of Pittsburg, a valuable paper on the necessity of culture studies for medical students; a paper by Dr. P. Maxwell Foshay of Cleveland upon his new method of determining the value of professional services recently outlined in the *Cleveland Journal of Medicine*, and another by Dr. James A. Spalding of Portland, Me., giving the personal experience of an ophthalmologist suffering from a sudden loss of vision and consulting first the optician and then the oculist for aid, showing the inefficiency of the former and the great help which the latter gave him.

The meeting concluded with the usual very enjoyable social session after electing Professor V. C. Vaughan, of the University of Michigan, President.

BOOK REVIEWS.

Nursing Ethics; for Hospital and Private Uses. By Isabel Hampton Robb, Graduate of New York Training School, Bellevue Hospital. J. B. Savage, Cleveland.

A careful perusal of this little work is warmly recommended to all who are already nurses or who intend to venture into the nursing profession, for very rarely have ethical principles been set down in a more attractive and readable style than this well-known author has done. The book will claim the attention of all who open it; doctors will appreciate the ennobling and oftentimes self-sacrificing duties of a nurse; nurses themselves will find much to instruct them and to define their responsibilities, while the probationer will get a clear idea of her work, and, if aware of her unfitness, may rid the profession of an undesirable member. Its adoption among the regular text-books of a training-school is warmly advised.

Modern Surgery, General and Operative. By John Chalmers Da Costa, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia; Surgeon to the Philadelphia Hospital and to St. Joseph's Hospital, Philadelphia. Third Edition. W. B. Saunders & Company, Philadelphia and London.

We welcome with pleasure the rapid appearance of this new edition of Da Costa's Surgery. That it has stood the test of time, its popularity among student and physician has shown. The original plan of the work has not been departed from, but, as in the previous edition, it has been found necessary to add considerable new matter to bring it up to the present day. The language is clear and concise, the description of operations to the point and the illustrations, among them quite a number of radiographs, excellent. The book will, no doubt, continue to enjoy a wide sale.

Human Placentation. An Account of the Changes in the Uterine Mucosa and in the Attached Fetal Structures During Pregnancy. By J. Clarence Webster, B.A., M.D. (Edin.), F.R.C.P.E., F.R.S.E., Professor of Obstetrics and Gynecology, in Rush Medical College (affiliated with the University of Chicago); Fellow of the American and Chicago Gynecological Societies, and of the Edinburgh Obstetrical Society, etc. A monograph containing 120 pages of text, with 233 illustrations. W. T. Keener & Co., Chicago: 1901.

This is a comprehensive but concise study of the human placenta, and presents a full account of the changes in the uterine mucosa and in the attached fetal structures during pregnancy. It is based upon investigations, extending through a period of eleven years, conducted by the author at the College of Physicians, Edinburgh, McGill University, Montreal, and Rush Medical College, Chicago. He has studied the uterus from actual specimens secured during all the successive months of pregnancy beginning with the second, in the first and second stages of labor, in the third stage (the uterus being secured by Porro-Cæsarian section), and during various stages of the puerperium. Cases of complete abortion in the early weeks of pregnancy have also engaged his attention. For the purpose of comparison the placenta and uterus were examined, in various stages of pregnancy, in the mouse, rat, rabbit, guinea-pig, pig, sheep and cow. The work is a monument of industry and careful, scientific investigation and is a most valuable addition to our knowledge of the subject. The author discusses the observations and conclusions of previous investigations and presents many valuable conclusions, but the book is principally noteworthy as being a repository of facts valuable and pregnant with future suggestion.

The Year-Book of the Nose, Throat and Ear. Edited by G. P. Head, M.D., and Albert H. Andrews, M.D. The Year-Book Publishers, 100 State street, Chicago, 1901.

This summary of current literature on the nose, throat and ear is well edited and very readable. Its abstracts are carefully made, indicating the main points in leading articles, so that the whole gives the reader a comprehensive survey of the latest additions to each of these fields of study. The arrangement by subjects and regions, giving together all of the same kind and referring by numbers to the Index of Periodicals, which in turn is supplemented by a good general index, is such as to invite to helpful knowledge with little effort. The work serves the purpose of the more formidable Index Catalogue with less cost and greater convenience. The volume is handy. The editors have made it valuable and available for both the general practitioner and the specialist.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Chronic Urethritis of Gonococcic Origin. By Drs. J. de Keersmaecker and J. Verhoogen. Translated and Edited by Dr. Ludwig Weiss. 8vo, 250 pages. Illustrated. William Wood & Company, New York.

Principles of Surgery. By Dr. N. Senn. 8vo, 700 pages. Illustrated. Third Edition. F. A. Davis Company, Philadelphia and Chicago. $4.50.

Uterine Fibromyomata. Their Pathology, Diagnosis and Treatment. By Dr. E. S. Bishop. 8vo, 322 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. $3.50.

Manual of Diseases of the Ear. By Dr. Thomas Barr. Third Edition. 8vo, 429 pages. Illustrated. The Macmillan Company, New York. $4.00.

ORIGINAL ARTICLES.

PSYCHIC EPILEPSY, WITH THE REPORT OF A CASE.*

BY J. W. COURTNEY, M.D.,

OF BOSTON;

ASSISTANT IN NERVOUS DEPARTMENT IN THE BOSTON CITY HOSPITAL.

IN view of the enormous amount of literature which has appeared in the last few years on the subject of epilepsy, the following statement of the late Dr. Landon Carter Gray, in an article written by him only five years ago, is both interesting and significant. He says: "The physician himself seldom sees an attack, even if he be the resident of a hopsital, for, while I have probably treated thousands of cases, I could easily count on my fingers all those that I have observed during the attack itself." Now, if Dr. Gray's utterance is true with regard to the ordinary convulsive attack, it is vastly more so with regard to the psychic-form—a fact which gives to a personally observed case of the latter type, such as is to be related, sufficient importance to make it worthy of record. But before proceeding to this, a brief preliminary review of our present state of knowledge on the general subject of psychic epilepsy would seem not to be out of place.

By psychic epilepsy we understand those peculiar pathologic alterations of consciousness and memory which may precede, accompany, follow, or even, according to certain observers, take the place of the epileptic fit. Patho-physiologically considered, such states of mind are regarded as the result of inhibitory or irritative explosions within that portion of the cerebral cortical territory which presides over psychic processes. Hence simultaneous motor disturbances, the result of a synchronous inhibitory or irritative explosion primarily within the motor cortical territory, are constantly lacking. Nevertheless, associated motor phenomena, sometimes of the most complicated and purposive types, do occur, and to account for them properly we must consider them as end-results of psychic processes. As a matter of fact, it is these very motor phenomena, which frequently manifest themselves in theft, burglary, acts of violence, murder even, that have lent to the subject of psychic epilepsy the great forensic importance which it possesses to-day. As Ottolenghi says: "It is to such epileptic accessions that we must often refer those enormous crimes which strike fear and terror to the heart of a community and make it, overwhelmed with horror, cry vengeance against the human beast, the ferocious assassin, who often is none other than a pitiable epileptic, irresponsible for his misdeed."

For a long time this close association between epilepsy and crime has engaged the attention of alienists and criminologists all over the world, and it is to their untiring efforts that our present comprehensive knowledge of epileptic psychopathic phenomena is due.

Before entering upon the consideration of the varied disturbances of consciousness and memory which constitute the clinical expression of the psychopathic phenomena, it may be well to state that the epileptic is particularly prone to illusions and hallucinations. As a matter of fact, the epileptic brain constitutes a fertile soil for the formation of both of these types of morbid phenomena, which may exist independently of the convulsive attacks, may provoke the attack, or occur in the attack itself, forming in the last named, as a rule, the psychic aura.

The disturbances of consciousness and memory proper, with their consequences, are, however, the factors in psychic epilepsy which are of the greatest medico-legal importance and deserve the most extended consideration. These have been divided by authorities into the two following groups: (*a*) Those constituting the so-called intellectual petit mal; and (*b*) those constituting the so-called intellectual grand mal.

But it should be borne in mind that although these forms derive their names from the grand and the petty convulsive attacks, they cannot be brought into any causal connection with them. Furthermore, that there is no correlation between the psychic attacks and the convulsive phenomena of the disease in one and the same individual.

Intellectual Petit Mal.—In the simplest form of this type the loss of consciousness may be so slight as to escape observation unless this be lengthy, complete and searching. Such losses of consciousness have been characterized as "absences or pauses of consciousness." In certain attacks the patient's glance becomes fixed in the distance, his face suddenly becomes pallid, his speech interrupted, his gesture arrested, and he remains apparently unconscious, and as if in an ecstasy. After a few moments consciousness returns, and he continues all forms of activity at the point at which he left off.

The obnubilation of the intelligence presents great variations in degree. At times it is so profound that the patient has absolutely no sense of what has happened; at others he sees vaguely the persons about him but does not hear what is said, or *vice versa*. And afterward he is practically

* Also published in the Medical and Surgical Reports of the Boston City Hospital, Eleventh Series.

never able to reply correctly to what is said to him while in the attack. Should the attack come on while he is walking about, the walk may not be interrupted. Sometimes it does not occasion a pause even in occupations which require delicate manipulation, as shaving, the patient being totally unaware that anything unusual has happened.

It is interesting to note here that Féré objects to the contention of many authorities that such manifestations are the result of inhibitory or irritative explosions in the purely psychic areas of the cerebral cortex, without similar synchronous explosions in the motor areas, because, as he says, whereas certain patients during the attack merely drop whatever object may be in their hands, others project it to a distance. This author further supports his objection by myographic tracings which show the presence of slight muscular jerkings in both upper and lower extremities, synchronous with the onset of the "absence."

Although the integrity of the intelligence seems frequently to be restored at the end of the absence, this is not always so. It may remain clouded for several minutes, during which the patient appears as if astonished and not in normal touch with the situation; or the obnubilation may continue for hours.

In the more prolonged and severe attacks of the intellectual petit mal type there may occur the most varied motor phenomena as end-results of perverted ideation. Such attacks often manifest themselves suddenly, after a short incubatory period of melancholic depression, by a condition of profound anxiety, and are characterized by marked confusion, considerable irritability, impulsions—all of which the patient may recognize as pathologic—and by imperative ideas. Overwhelming *tedium vitæ* may take possession of the patient, and often betrays itself in suicidal attempts of the most loathsome sort. During this same condition certain patients repeat incoherent words, take off their clothing, strike those about them, or commit acts of theft and incendiarism; others exhibit their genitals, while others still, yielding to impulses, leave their homes and walk straight before them for a longer or shorter period of time. It is among this last group that we find those interesting cases of ambulatory automatism of long duration, in which the patient may go about for many days, or even weeks, performing the most complicated acts, without attracting attention to his condition, and may not come to himself until he is hundreds of miles from home. During the whole period of this so-called automatic state the patient may give proof of his power of initiative, act just as he would in ordinary health, retain a recollection for memories already acquired, and not lose consciousness of such automatic acts until he comes to himself. This twilight state of consciousness (the "Dämmerzustand" of the Germans and the "stato crepuscolare" of the Italians) together with the variations in the character and degree of amnesia to which it leads, are among the most important considerations, from a medico-legal standpoint, in the whole domain of epilepsy, and will be considered more fully later in connection with amnesia.

Intellectual Grand Mal.—The question whether this type of epileptic psychosis is an absolute equivalent to the grand convulsive attack, as it is held to be by certain observers, is still an open one of great interest and importance. Legrand du Saulle claims that every insane outburst of this type is invariably preceded by some well recognized epileptic manifestation, such as rudimentary and abortive paroxysms or a nocturnal attack, and alleges lack of thoroughness of research on the part of those who regard such outburst as a pure equivalent. Be this as it may, there is certainly one fact in reference to this particular type of psychosis which seems to be proven by accumulated experience, namely, that it can never in a given case, be regarded as the first symptom of epilepsy. To establish its claim to be considered as epileptic in character other well-recognized manifestations of the disease must be shown to have preceded it. The medico-legal importance of this fact will be apparent when we come to the question of diagnosis.

Attacks of intellectual grand mal usually occur after very brief prodromes, and manifest themselves, in contradistinction to the ordinary petit mal types, by impulsive acts of the greatest ferocity directed against the sufferer himself or against others. The basis of these impulsive acts is usually composed of a mixture of anger and fear sensations, and of terrifying and threatening hallucinations. After committing acts of the most brutal ferocity, the patient may sink into a profound slumber, surrounded by the most damning evidences of his crime, and awake therefrom with a complete amnesia for the attack and everything connected therewith. In certain cases the attack may last for several hours or several weeks, and in the latter type a remittent character is not infrequently observed. During these remissions, which may last for some hours, the patient may be clearer and quicter, or he may sink into a deep sleep, from which he awakes fully deranged as before, and either stuporous or thoroughly excited.

According to Falret and others a primary incoherence or dissociation of ideas is the most essential feature of the disease-picture. All other symptoms group themselves in the most widely varying intensity and manifoldness about this psychopathologic basal phenomenon, which also plays the greatest part in the dreamlike character of the attack. The special form which the psychosis will take in a given case is determined by variations in the pathologic play of the passions, as well as by the number and content of the hallucinations. If there is a marked inhibition of thought processes, the element of incoherence retires into the background, and a marked stuporousness takes its place. Patients of this type remain mute, unparticipative, withdrawn within themselves, until a more powerful sensation of

fear or anger, or a more active hallucination arouses them from this treacherous apathy and impels them to deeds of the most ferocious violence.

When incoherence alone is at play throughout the attack the patient is in a condition of the most marked motor excitation, which betrays itself by purposeless and senseless acts, by the garrulous externalization of rapidly succeeding ideas and, at the height of the attack, by absolute verbigeration. And it is easy to determine, by his mimicry, gesticulations and speech, that he is under the spell of visions or of hallucinations of other special senses, or of illusions. He is fully disorientated, and the threads which bind him to the outer world are completely severed. He leads, in reality, a dream life, which, dissevered from all normal connections with the outer world, is governed only by fragmentatively arising ideational complexes or by hallucinations and illusions. In exceptional cases the hallucinations manifest themselves with great sensual liveliness. Animal shapes, deluges, representations of theft and murder crowd upon the patient and occasion ineffable terror, or incite him to defence or flight; or divine voices, rejoicing angels, or transfigured relatives deliver joyous messages to him. He sees soldiers marching, hears patriot songs resounding, cannons thundering, drums beating and trumpets calling; he rushes about the room in an ecstasy of patriotism, sings national songs, and cries "hurrah!" On the other hand, it may be shrieks from hell he imagines he hears; devils may assail him, and dreadful cries resound about him; a horrible smell may fill the room. In this case the patient huddles whimpering beneath the bed-clothes or cowers trembling in a corner of the room to escape the onslaught. He may even run swiftly from place to place in search of shelter, and this procursive tendency has led, on the part of certain observers, to the mistaken idea of a procursive epilepsy (epilepsia procursiva) as a clinical entity of the disease, whereas the phenomenon is in reality due to an insistent and monotonous cycle of imaginations, or to certain hallucinations.

The Pre- and Postepileptic Psychoses.—These forms of transitory mental disturbances are, to a certain extent, to be considered only as prolongations of the aura or as outgrowths of the soporous after-stage. The postparoxysmal forms excel by far in frequency and extent. The preparoxysmal consists principally in increased irritability of the temper, great anxiety, markedly inhibited ideation, monotonous hallucinatory excitation or impulsions—less often in an extravagant good humor—and generally leads merely to motor reactions of a few hours' duration, which take the form of compulsory disordered activity or of acts impelled by fear and anger. The postparoxysmal psychoses, on the other hand, present much closer analogies to the psychopathologic phenomena of the so-called epileptic equivalent. They have been divided by Binswanger into the following groups:

(*a*) Merely stuporous conditions, the result of inhibition of all intellectual and motor conductivity.

(*b*) Attacks with ordered automatic acts.

(*c*) Attacks with systematically arranged hallucinatory series, like certain dream-pictures.

(*d*) Attacks with stormy hallucinatory irritative phenomena, accompanied by marked incoherence and impulsive acts of violence.

A combination of two or more of these groups may be present in any case, and the clinical aspect naturally varies accordingly. It is noteworthy that protracted stuporous conditions, which may extend over many days or even weeks, prevail more commonly in the postparoxysmal conditions than in the equivalent, so called. Hence, we may have mutism, fixed and expressionless glance, slow pupillary reaction, diminution of the skin and tendon reflexes, varying flaccidity and cataleptiform rigidity of the body musculature, total analgesia of the skin and mucous membranes. If such attacks last for days they are generally interrupted, during periods of several hours' duration, by marked motor excitations, such as: Verbigeration, simple and combined compulsory acts, deeds of violence, etc., either with or without a recognizable hallucinatory basis.

As a rule this severe type of attack follows closely in the wake of the frequently repeated and serial form of epileptic convulsions. The convulsive series may be made up of the most varied combination of complete, rudimentary, or abortive attacks. The best measure of the probable severity is the longer or shorter interval which prevails between individual convulsions; the shorter the interval and the greater the mental and bodily degradation which follows, the more protracted and severe will be the psychosis at the end of the series. Binswanger has observed, in a less common group of cases, where the transitory psychosis follows upon a single complete or abortive convulsive attack, that this outburst is the probable result of a postponement, by treatment or otherwise, of an attack which, if not interfered with, would tend to recur frequently.

In the amnesia which is intimately associated with all types of psychical epilepsy we have a subject of the greatest scientific and forensic importance, and the variations which it presents in form and degree lend a peculiar interest to its study. In the most prolonged "absences," those which may last for days, months or even years, during which the patients think and act in a fashion analogous to their normal state and have a memory for their acts that ceases only when they "come to themselves," as it is called, we often observe an amnesia which is profound. This probably arises from the completeness of the doubling of the personality which takes place; there being not a single thread which binds the intellectual processes of the "twilight" with that of the normal state of consciousness. Complete amnesia of this type usually follows closely upon the very brief and violent insane outbursts which at times constitute the psychic equivalents of the

epileptic convulsion. Here the amnesia is probably to be explained on the ground that in the pathologic play and counterplay of inhibitory and irritative processes which dominate the psychic activity of the epileptic, the factors are not present that give rise to the production of memory-pictures in the ordinary course of associated ideas.

In other cases the amnesia is not so deep. In the less developed forms of the crepuscular state the memory defect is less marked. There are connecting links between the normal and abnormal which are made up of fragmentary memories of acts and experiences occurring during the attack.

One of the most interesting types of amnesia which occur in connection with epilepsy is the so-called "retroactive" type, in which the loss of memory goes back farther than the attack itself. This retrograde amnesia has considerable forensic importance.

To establish the diagnosis of psychic epilepsy frequently requires a great deal of acumen combined with endless patience and pertinacity. From time to time epileptics are put on trial for the most widely varying criminal acts, from petty theft to murder, for which they are not responsible and of which they may have not the slightest memory. On the other hand, the plea of irresponsibility, the result of an epileptic psychosis, is often put forward by astute criminals to shield them from the law. Consequently it behooves the medical expert to have in mind the clearest possible understanding of the epileptic psychoses with their manifold manifestations. Before one can say that he is dealing in a given case with an epileptic psychosis, he must prove absolutely by such unequivocal signs as convulsive attacks, fully marked, rudimentary or abortive, that the patient before him is really an epileptic. It has already been emphasized that the epileptic psychosis is never the first symptom of the disease, and recorded cases all go to prove farther that it does not suddenly appear out of a clear sky at some remote period in the life of an individual whose only claim to epilepsy is based on one or two convulsive attacks which occurred in infancy or early childhood.

In the case of a crime (murder for instance) alleged to be committed during an attack of epileptic insanity and to be followed by retrograde amnesia, there are many factors to be considered before the truth of the allegation can be admitted and the irresponsibility proved. In the first place it should be remembered, as Féré has pertinently shown, that an individual may leave his house, descend his steps, cross a garden walk and then lose all memory in consequence of a shock which he has sustained on putting his foot upon the sidewalk, but this loss of memory does not prove that the individual was either unconscious or irresponsible when he shut the door of his house. In the same way an act committed under the spur of an uncontrollable passion may leave behind it a retrograde amnesia of marked degree both for the act and the circumstances leading to it, but it does not prove irresponsibility. This is particularly emphasized because there are cases on record where postepileptic retrograde amnesia and irresponsibility have been alleged and successfully sustained in defence of criminal acts, the results of pure outbursts of passion. On the other hand, it is also to be borne in mind, that an epileptic, even during the most violent period of his insane outburst, may reply to appelations and hurl at each of the onlookers appropriate objurgations, but that while this may be taken as an index of a certain degree of consciousness, it cannot also be assumed as evidence of responsibility.

In certain cases, where amnesia is not retroactive, the patient on coming to himself, with evidences of his crime on every hand, does not seek to excuse himself. But this does not always follow, and Féré and Legrand du Saulle have reported cases when the patient alleged the most improbable reasons for his deeds. In other cases still the amnesia is retarded, and may not be complete for several hours after an attack.

The character of the crimes to which epileptic insanity usually leads has already been alluded to, and it is of diagnostic importance to keep in mind the fact that such crimes, as a rule, are the automatic execution of a preëxisting idea, whether normal or pathologic and that their gravity usually varies with the ordinary sanity and calling of the subject. If, for example, he is ordinarily sound in mind and has only professional preoccupations, his insane acts during the attack will be vastly less dangerous to himself and the community than if he is constantly unsound, subject to homicidal or suicidal impulses, or is a habitual criminal. As a matter of fact, many criminals are also epileptics, and Ottolenghi goes so far as to see in the mental, moral and physical habits of many habitual criminals congenital and other evidence which tends to prove that their whole existence is one protracted "twilight" state much diluted, so to speak.

Alcohol as a factor in the production of psychic epilepsy is one of paramount importance. The epileptic brain is one which is easily upset by even small amounts of such a marked nervous irritant, and the result is frequently an attack of insanity. In cases of epilepsy due to craniocerebral traumatisms in which, as every neurologist well knows, intolerance of the brain for even trifling amounts of alcohol is particularly striking, it becomes a nice question as to the responsibility of the individual for crimes committed during an outburst of epileptic insanity produced directly through the agency of the alcohol. Apart from this, pure alcoholic mania has been confounded with the epileptic type. A proper investigation of all the circumstances attending the onset, together with careful observation of the patient after the attack should easily suffice to differentiate. Genuine alcoholic epilepsy usually comes on very late in life, after many years of abuse of this stimulant.

The so-called *raptus melancholicus* has in certain cases been mistaken for the epileptic accession. This form of maniacal outburst, which sometimes occurs during the course of melancholia and is marked by violent impulsions of various kinds, is to be differentiated from the epileptic variety by a careful consideration of the previous history of the case, and by the fact that the acts which immediately precede the *raptus* are never followed by that apparent tranquility of mind which is possible in the crepuscular state of consciousness which precedes or constitutes the epileptic psychosis. In addition to this the ideas of persecution which impel the melancholic to violence are always more fixed and persistent than in the epileptic. Finally the intermittency of all the epileptic prodromes is in sharp contrast to the fixity of the melancholic.

Transitory mania and psychic epilepsy have so many bonds of affinity that many cases of the former are confounded with the latter. In any case the differentiation is simple, if one can establish the fact of preëxisting epilepsy, of no matter what type.

The distinguishing feature between the "twilight" condition of epilepsy and the merely somnambulistic state is that in the latter there is almost invariably lacking all impulse to deeds of violence, so common to the former.

From all that precedes we may finally conclude: (*a*) That the psychoses of epilepsy have very definite and immediate associations with other manifestations of the disease; (*b*) That the plea of irresponsibility for criminal acts alleged to have been committed while an individual was suffering from epileptic mental alienation should be considered invalid, unless other and irrefragible manifestations of the disease can be adduced; (*c*) That vague and ill-defined convulsions, which date back to infancy or early childhood, do not constitute such other manifestations.

The case to be reported comes under the head of intellectual petit mal. It is of traumatic origin and presents such clinical features as "absences" of consciousness, amnesia, and automatic acts.

The patient is an unmarried man of thirty-three years. He was born in England of Scotch parents, and is by occupation a waiter in a hotel. The family history is free from any taint of mental or nervous disease and the patient's parents are both alive and well. There is no history or evidence of venereal disease. Up to eight years ago there was very moderate habitual use of malt liquor; little since. Tobacco, four ounces per week. Up to fifteen years ago the patient was a well man in every respect. At that time he fell from a cherry-tree, striking, he thinks, on his head. He got up, however, almost immediately and began to walk, and did not "come to himself," as he puts it, until he had gone several miles. He recognized that he had gone a long distance, but could not tell why, although he was aware that he had had a fall. He was all right after this for several years, but then began to have "fainting" spells, during which his mind was a blank. Four years ago these spells began to be preceded by a bad taste in the mouth, and as unconsciousness developed the patient would clutch at surrounding objects. In such attacks he has burned his hands several times by clutching at a red-hot stove. Since this time there have been pretty constantly recurring attacks of ambulatory and other automatic acts. He says that he may be walking along the street, when his mind suddenly becomes a blank and he continues on indefinitely, knowing absolutely nothing about what he is doing or where he is going. On one occasion he remembers going into a saloon and asking some one to drink with him, but does not remember getting up to the bar. Several hours later, when he had regained consciousness, he found himself under arrest for drunkenness. His memory is poor, but between attacks he manages to do his work fairly satisfactorily. His appetite is good and his bowels regular. He sleeps well, as a rule, but there are times when he does not sleep at all for two or three nights running, and he finds that his mind is not clear on these occasions. His eyesight and hearing have not failed. Up to this date (May 28, 1900) there has never been any attack of the grand mal variety. Examination to-day (May 28) is absolutely negative from a physical standpoint. Mentally the patient is sluggish and gives evidence of marked impairment of the memory. Close inquiry fails to reveal any hallucinatory or delusional precursors of the attacks. Subsequent notes are as follows: June 15.—Three days ago attack while riding home in cars. Did not get off at destination but continued to end of route and back again, paying two fares. Did not come to for half an hour and got home before his head was very clear. Ordered to increase bromide to gr. xx. t. i. d. June 29.—Two attacks this A. M., one here at the clinic. In this latter he sits staring at a newspaper which he holds semi-inverted, as if in the act of turning it. The pupils are equal, moderately contracted, and irresponsive to light. The face is congested and sweat pours from the forehead; the patella reflexes are absent. He pays no attention to questions, even when they are put to him in loud, sharp tones. There are no convulsive movements. Given a pasteboard card, he tears it industriously in layers, and then demolishes a block of prescription blanks, slip by slip. When nudged or shaken, he merely grunts and continues what he is doing. Ten minutes after onset he answers questions somewhat, but cannot tell where he is. He is then given a promissory note for ten thousand dollars made payable to me, for value received, and asked, after reading it, to sign it. He does so, and is then asked to add the date. In response to this he looks at the newspaper in his lap, asks what the date is, and, when told, repeats his question several times; finally adding date to

the note. He is then told to read the note aloud and does so, calling $10,000—ten dollars. He is told that the sum is ten thousand dollars and asked if he meant to sign it. He says he did. Five minutes later he is shown the note again but remembers nothing about having seen or signed it. A half an hour after the onset the patient is almost fully conscious and remembers nothing whatever about the attack or anything connected with it. His knee jerks are now present and normal. The pulse and respiration have been normal throughout.

Nothing of note with reference to the case is recorded from the above date until August 6, when the following record was made: "The patient had an outspoken convulsive attack on the night of August 3. Given bromide gr. xx from then on. Had one or two other slight spasms. His mother let him go out alone last evening and he has not been seen since. Advised commitment to epileptic colony at Munson, when found."

In view of the general description given of intellectual petit mal it seems hardly necessary to enlarge upon the diagnostic features of this particular case. The forensic importance of such an act as signing the promissory note needs only to be mentioned to be appreciated. With regard to the attack which occurred when the patient entered the saloon and invited the person he met there to drink with him, an attack which led to his subsequent arrest for drunkenness, there appears to the writer to be two interpretations. Either that he did actually take a drink, which precipitated the attack and led to a complete amnesia of a retroactive type, or that the attack came on just as he started to take the drink. If the latter theory is correct, the amnesia really goes back only to this point; but it is easy to understand that the patient himself believed, on finding himself under arrest, that he had actually taken the drink and had become intoxicated thereby.

THE MEDICAL EXPERT EVIDENCE IN THE CASE OF THE DAVIS BELLEVUE HOSPITAL HOMICIDE.[1]

BY R. L. PRITCHARD, M.D.,
OF THE NEW YORK BAR.

This case, recently tried in this city, has brought the question of medical expert evidence once more prominently before the public. The accused was a nurse in charge of the Insane Pavilion, and he was charged with having caused the death of a patient through violence. Three witnesses testified for the prosecution that they saw the accused nurse strike the patient Hilliard, and pull on a sheet which he had placed around Hilliard's throat. The accused nurse, Davis, as a witness in his own behalf, admitted that he had used restraining force upon Hilliard, and that he had slapped him. The defense was that Hilliard did not die from the effects of the violence.

In no recent case has the issue of the defendant's guilt been so entirely dependent on medical expert evidence as in this case. The defense examined eight medical witnesses, and amongst them were men of the highest standing in the medical profession. The prosecution, not to be left too far in the number of medical expert witnesses, examined five experts, and amongst them were also men in the front rank of the medical profession. The experts on one side differed from those on the other—this is not unusual; but to emphasize their differences, the District Attorney described the testimony of the expert witnesses as a race of liars.

The question which concerns the student of legal medicine is whether the science of medicine is still so far speculative that five prominent physicians can testify that death resulted from strangulation induced by fracture of the hyoid as a consequence of violence used; whilst with equal certainty, eight prominent physicians can testify that death was the result of dilatation of the heart, and that the violence could not have fractured the hyoid bone. With all respect to the District Attorney, neither the experts on one side of the case nor on the other can be charged with wilful misstatements. The medical issues in this case, upon which the medical experts differed, were not of a subtle nature dependent upon microscopic bodies one-ten-thousandth of an inch in diameter, but upon lesions of a gross nature. These lesions were the postmortem appearances of strangulation, and the fracture of the hyoid bone by pulling on a sheet around the throat. With differences in the evidence so striking as they were in this case, and the expert witnesses so eminent, it would be pertinent to inquire whether the District Attorney and the able counsel for the defendant had presented the medical facts in the case, so as to make the differences of the expert witnesses almost impossible? In other words, whether the differences are not due to counsel, who were wading in a science to which they were strangers, rather than hold responsible thirteen members of acknowledged ability in the science under investigation.

The legal profession refuses to assume any responsibility for the differences of medical opinion on the ground that it is the duty of the lawyer to present the best side of his client's case. This is doubtless true as to the lawyer's duty, but when the result of long drawn out medical testimony is negatived by a mass of contradictory opinions, has counsel done his full duty to his client when he has barricaded his case with favorable expert opinions? What he has done his confrère on the other side of the case can accomplish by arranging the facts so as to elicit opinions favorable to his side. Criticism of expert evidence looks upon the difference in the opinions, and but seldom compares

[1] Read before the Medico-Legal Society, March 20, 1901.

the facts upon which the opposite opinions were given. Counsel can hardly be content because his expert concluded favorably to his side of the case. If his expert opinions are founded on a full and fair statement of facts, the same statement of facts should be submitted to the opposing expert in cross-examination. The expert, when cross-examined, may cross-examine his cross-examiner, if permitted to do so, but cross-examination is the lawyer's field if he has a full knowledge of all the facts and he keeps to them. By doing so, the opposing expert testimony will lose in weight by the qualifications added to answers already given, or by evasion of material questions.

Was the expert medical evidence in this case of the People against Davis brought out on a full statement of facts? Counsel for the defendant may not think that this was necessary on his part, as he has secured an acquittal of his client. But how far was his success a fortuitous accident, which could not be trusted to on other occasions. As the medical issues were framed by the District Attorney, did he make clear all the evidence of Hilliard's death, so that reasonable men could only read in them strangulation? The facts of the postmortem examination were mainly congestion of the internal organs and imperfect aeration of the blood. These are symptoms of strangulation, but they are also symptoms caused by dilatation of the heart. If the District Attorney knew as much about strangulation as he does about law, he would not have sought a verdict implying death from strangulation on the facts presented by him. How then did the people's expert witnesses testify that death was caused by strangulation? Not by relying on the postmortem appearances, but by taking into consideration extraneous facts with the postmortem evidences in the people's case. On the other hand, the defendant's experts excluded from their consideration the same extranenous facts, and found the morbid evidences insufficient to prove strangulation. The opposing medical expert opinions were, therefore, made upon the weight given by each on other than medical data. The District Attorney was deficient on a statement of facts pointing to strangulation; and the defendant's counsel—though successful—was deficient in not submitting to the people's experts the absence of these evidences. However, as defendant's counsel was successful, his deficiencies will sit lightly upon him. And yet, as a scientific man, he must realize that he has achieved a result for which circumstances must be largely credited.

On the question of the fracture of the hyoid bone by means of a sheet around the neck, the people's experts did not go far enough when giving their opinion that it could be produced in this manner. The fact that eminent surgeons and pathologists doubted it, should have called from them such explanation of its probability as would have carried conviction. Not to have done so left a reasonable doubt, which the jury properly gave to the defendant. The hyoid bone is no part of the skeleton. This bone does not articulate with any other bone, and on this account its mobility is only limited by the soft structures through which it runs. This bone is a ridge acting as a center for a large number of muscles. When compression is applied over this bone by means of a sheet, which is to some extent yielding, the pressure will bear more upon the muscles above and the musculo-membranous space between the hyoid bone and thyroid cartilage. The direct pressure capable of breaking the bone, must be such as will firmly grasp it, and compress it more from side to side than from before backward. Still, compression over and about the hyoid bone is not without serious results to the bone itself, but the effect is not due to direct force. The result of the pressure is to interfere with the free entrance of air, and this interference with respiration causes spasmodic contraction of the muscles which act upon the hyoid bone. The muscles acting upon the bone from below are four, and those acting from above are ten. The hyoid bone is subjected to violent and irregular contraction of the muscles inserted into it, with the effect of the bone breaking, as a result of this muscular contraction. Fracture of the hyoid bone caused by muscular action is recognized in all surgical works which treat of this subject. The attention of the experts having been directed to the direct force of the compressing sheet, it was fairly open to doubt whether the injury could follow directly from this violence. Even the defendant's experts would have admitted the possibility of the bone breaking from muscular action. It is too much to expect of the expert witness that he should take into consideration every possibility, indirect as well as direct. That is impossible, as the mind, however honest, decides on facts placed before it. It is counsel's duty to marshal the facts and submit them fully.

Medical expert testimony is not a race among liars. Medical expert testimony, as this case demonstrates, is more often defective from the manner of its presentation than an assumed yielding of the expert witness to whatever opinion is desired of him. Medical expert evidence has the indifferent witness who makes the possibilities of medical science his excuse for almost any opinion demanded of him. That medical witness exists, and it behooves the medical profession to brand him as a canker eating into their body professional. They alone can do it, as they are the only ones capable of weighing an opinion made possible by the possession of a medical diploma. But this last class of medical expert evidence is not found in a trial of great public interest, and where the medical witnesses are the foremost members of the medical profession.

Appointment of Dr. Christian.—Dr. Frank L. Christian, formerly a house physician at Bellevue Hospital and more lately medical officer of the Eastern District Reformatory, has been appointed Medical Superintendent of Elmira Reformatory.

OBSTIPATION. [1]

BY STERLING B. TAYLOR, M.D.,

OF COLUMBUS.

PROCTOLOGIST TO GRANT HOSPITAL, ETC., COLUMBUS, OHIO.

Obstipation, as its name would indicate, is an obstructive costiveness and is to be differentiated from functional costiveness, intentional, habitual delay of bowel movement, and constipation. It is a far more common disease than the profession is prepared to admit.

That type of costiveness which deserves and has received the name of obstipation is dependent upon some mechanical or foreign interference situated in the rectum or sigmoid flexure. Functional costiveness is that condition which may exist as the result of errors in diet or neuroses, exhibiting itself by small daily movements, leaving a residue to accumulate in the intestine. Wirthington[2] says "There is no sharp line separating constipation from health." We claim there is a very clear line separating obstipation from the two lesser evils, constipation and functional costiveness, hence sharp demarcation between health and obstipation.

In constipation there is a sluggishness of peristalsis which consequently delays bowel movement, but eventually there is an effective and satisfactory effort at defecation. Just the reverse of the latter proposition is true in the condition under discussion, as there is a constant unrequited desire which is only partially relieved by using such adjuncts as physic and enemata, producing a stool which is either liquid, semi-solid or tape-like in form, and which leaves still that uncontrollable desire for further and complete defecation.

The name obstipation is derived from two Latin words, *ob* meaning "against" and *stipo* to "stuff or cram." We therefore have in obstipation a stuffing or cramming against an obstruction which may be found under any one of the following heads: (1) Compression from without; (2) blocking up of lumen of canal; (3) constriction arising from disease of gut wall; (4) hypertrophy of normal rectal valves; with consequent interruption of lumen of canal and accompanying distortion of gut above obstruction, the latter condition begetting an atonic state.

Ross, in discussing obstruction of the bowels, classified the causes under the first three of these heads, but failed to find the fourth and most important cause, which we place under the fourth division. We will give but brief attention to the first three and confine ourselves principally to the fourth topic:

First, compression from without may be caused by carcinoma or sarcoma involving adjacent organs with the infiltration of surrounding tissues; by enlarged prostate or malposition of uterus and other organs; by adhesive bands which bind down the gut, thus decreasing its caliber, etc. We have in mind one case in which proctoscopy revealed post-operative adhesions. A few weeks since we saw a sarcoma of the sacrum and ilium which produced a decided narrowing of the lumen of the rectum.

Second, the lumen of the canal may be occluded by foreign bodies introduced either *per orem* or *anum*, or forming within the personal economy. This includes an endless category of bones, buttons, nuts, fruit-pits, metallic substances and possibly gall-stones.

Third, constrictions may arise from benign disease of the gut-wall such as dysentery, adenoids, and the specific diseases—syphilis and tuberculosis—and from the malignancy of carcinoma and sarcoma.

Fourth, hypertrophy of the rectal valve as a cause of obstipation. To quote Martin, "One must go to the histologist and not to the mechanical engineer for the definition of an anatomical valve." He tells us that "Shäfer and other histologists agree that an anatomical valve is composed of a superficial layer of epithelium, next a layer of fibrous tissue, and circular muscular fibers at the base. Martin has made sections of many rectal valves, and found that "the most typical partake of the character just mentioned, while many are atypical; some contain fibers from the longitudinal muscular coat; many have a paucity of fibrous tissue; in others the fibrous element appears to be far removed from the mucous free border of the valve, and in others the circular muscular fibers may be sparse or in abundance."

The rectal valve spans half the diameter of the rectum, is semilunar in shape, and must be considered as an anatomical entity in studying the mechanism of defecation. The existence of the normal rectal valve must no longer be doubted Dr. James F. Baldwin, in discussing a previous paper by the writer on this subject says: "As to these rectal valves, I have seen them in the dissecting-room, sometimes well marked, sometimes indistinct. When, therefore, Dr. Martin first described them and brought them in as pathological factors in the production of obstipation, I accepted his statements with full credence." Cooke, Pennington, Earle, Gant, and in fact every man who has had the opportunity to see a valve, either ante or postmortem, is thoroughly convinced of their existence. Gray and Morris, authorities whom all recognize, state that the rectal valve is an anatomical factor worthy of consideration.

As a rule, there are three valves, but there may be either more or less. I remember seeing one case in which the number was seven. All people, with the usual exception to the rule, are given the normal rectal valve. Every organ of the body is subject to pathological change, and these structures get even more than their share, as their position is such that they are continually exposed to violence. The latter may be taken to mean traumatic, such as the injury to a valve by the passage of some rough or irritating body,

[1] Read before the Mississippi Valley Medical Association.
[2] Ref. Handbook of the Medical Sciences.

or their immersion by poisonous or acrid discharges. Adding the cases arising from the above causes to those cases of congenital malformation, we consider that we are justified in giving special prominence to the fourth cause of obstipation, before mentioned.

One needs to see a demonstration of the existence of the normal valve, and then to see one that has been thickened and enlarged to appreciate and understand how these valves may not only induce constipation, but acutally become the obstructive agent in obstipation. Martin, Cooke, and the writer have on previous occasions very properly claimed that it is the office of the normal valve to beneficially retard the descent of the fecal mass. We know this proposition will hold good, because we have by practical work demonstrated that the function of the rectal valve is to support any matter that is voluntarily or involuntarily placed on its upper surface. We have frequently seen accumulations of feces, mucus, water, and after surgical operations, blood, retained in the pocket or on the valve shelf. For example, take a valve that we know to be one that obstructs; place a marble, a pledget of cotton, or some other substance on the upper surface of the valve, and it will remain there until removed. Or pass a hook over a valve, make traction at right angles to the valve and it will not be effaced. After section of such valve has been made by Martin's method, any similar foreign body will be retained on the valve with great difficulty.

One valve may cause all the trouble. Usually two are at fault, but all may be affected.

How may we know that it is a hypertrophy of the rectal valve that causes obstipation? By taking a complete history of the case, arranging subjective symptoms according to the law of cause and effect, make a presumable diagnosis, then examine or have an examination made with the proper method and instruments. The unequipped will find that it will be frequently impossible to confirm or disprove their diagnosis, as it is futile to attempt to see even the first valve with the older methods, even under anesthesia. One of the best surgeons in the State of Ohio attempted to explore this field with the finger, with the ordinary speculum without an anesthetic; then anesthetized the patient and employed the same means, still with a negative result. The patient was then sent to us. He was placed in the Martin posture, the Martin proctoscope was used, bringing the entire field into view, from the levator and to the third chamber of the rectum, showing an anatomical coarctation of the first and second valves. Their propinquity was such as to offer almost a complete obstruction. The third and fourth were also found to be hypertrophied sufficiently to render a valvotomy necessary on all. This man's obstipation had continued for six years. A complete history of the case may be found in the *Columbus Medical Journal*, Nov. 20, 1899.

It is often difficult in this class of cases to be able to say just how much of the trouble depends on hypertrophy of the valve and how much is caused by the consequent angulation of the gut due to dilatation. Frequently valves are found which are complicated by an angulation and it requires considerable practice to be able to dispel the latter so as to properly measure the trouble caused by the former. No man can become so expert in this line of proctological work that he can essay to do away with the obstructive agent without proper tests and examination. But as a rule, even the inexperienced would have little trouble, with approved instruments and position, in being able to see the semilunar valves that span half and sometimes more of the circumference of the gut.

We recently saw and operated on a male patient for Dr. Morgan, of Washington, O., in the presence of his own physician, Dr. Shriner, and Dr. J. I. Davis, of Shawnee, Ohio. In this case there was a condition which would almost be analogous to the annular hymen, with which all are more or less familiar. There was a slight interruption anteriorly of about one-fourth inch. The operation was successful, the valve section radically relieved this patient and he is now no longer constipated.

Other men, Martin and Cooke especially, can doubtless give just such instances as having occurred in their own practice. If this case could only have been seen by doubting medical men, there could have been but one verdict coming from all—that the rectal valve does exist. Those who do acknowledge the existence of these valves and that they are normal structures, will doubtless be willing to agree that we may have a pathological condition existing at some time, such as an ulceration, edema or atrophy. If this can be granted, as it should be, it would not require much more work for the average mind to say that there can be a hypertrophy. If the normal valves retard the descent of feces beneficently, it is very plain that a valve increased in size to such an extent as to become pathological would be malicious in its hindrance of the descent of the normal contents of the bowel.

Symptoms.—The existence of hypertrophy of the rectal valves is evidenced by obstipation. This condition is, as its name would imply an obstructive constipation and presents "classic" symptoms, which we shall try to enumerate in a simple and clear way: (1) Chronic irregularity of bowel movement; (2) frequent, partially-successful attempts to evacuate the bowels; stool flattened laterally; (3) an inordinate desire for successful defecation; (4) a feeling of distension over course of colon, more marked in descending segment and at the colosigmoidal angulation, or over this point there is actual pain preceding an evacuation; (5) inability to pass gas freely and when gaseous distension is great, pain is felt over course of genitocrural nerve; aching in sacral region and down thighs; (6) mucus discharged independently or clinging to the fecal mass, clear, dirty, or sanious in character; (7)

evidence of auto-intoxication, which may be, usually is, manifested by headaches, neurasthenia, melancholia, anemia, insomnia, morning temperature subnormal; 4 p. m., temperature, 99°-99.8° F., (8) the appetite is fitful, tongue bearing white coat which refuses to be removed by frequent washings.

The above eight classifications of subjective and objective symptoms would warrant a presumptive diagnosis of hypertrophy of the rectal valves. This may be proved to be correct or incorrect, as the case may be, by a painless exploration of the rectum with the proctoscope. This is accomplished by placing your patient in the Martin posture (modified knee-chest), having previously made preliminary examination to make sure that proctoscopy would be admissible. Select protoscope No. 1, insert obturator—warm instrument—place point against anus, order patient to bear down, and insert. Withdraw obturator, when rectum will be seen to balloon, exposing its entire mucous surface below first valve and the valve itself, when each valve may be successively and successfully exposed and tested.

The treatment of hypertrophy of the rectal valve may be palliative, in the shape of massage, enemas, diet, etc., or radical. Radical treatment consists in a division of the free border of the valve, which is rendered tense by a band of fibrous tissue. In some cases operated on by the writer the band offered almost as much resistance to cutting as cartilage would. After division of the free border is made, the incision should be continued down almost to the gut wall, great care being taken not to overreach the safety limit. Sutures should be placed one in angle of wound, one on either side, to avoid hemorrhage and union by granulation. A tampon of surgeon's cotton wool, dusted lightly with Monsel's powder, may or may not be introduced as a further guard against hemorrhage. After-treatment consists of daily lavage and strict attention to diet, allowing only those articles of food that do not produce gas or a solid stool. This operation is one of the most delicate in surgery and should not be undertaken by any one without proper equipment and thorough knowledge of its technic.

344 East Rich Street.

A STUDY OF SOME COMPLICATIONS AND SEQUELÆ OF TYPHOID FEVER.

BY H. A. HARE, M.D.,

OF PHILADELPHIA;

PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE AND PHYSICAN TO ITS HOSPITAL;

AND H. R. M. LANDIS, M.D.,

OF PHILADELPHIA;

ASSISTANT IN THE OUT-PATIENT DEPARTMENT OF THE JEFFERSON COLLEGE HOSPITAL.

(Continued from page 945.)

Respiratory System in Well-Developed Stage.—Croupous pneumonia is a fairly frequent and a serious complication of typhoid fever, occurring during the course of the disease in 15 out of 829 cases at the Johns Hopkins Hospital. David Melville[126] noted pneumonia in 11 out of 295 cases occurring in the epidemic at Ladysmith, South Africa. In only one case, a double pneumonia, did death occur. There is a great diversity of opinion at the present time in regard to pneumonia occurring during the course of typhoid fever. It has been designated by the French writers as pneumo-typhoid, and is supposed to be due to the typhoid bacillus. Clinically it presents every evidence of an ordinary croupous pneumonia except for the finding of Eberth's bacillus in the sputum instead of the micrococcus lanceolatus. Osler evidently limits cases designated as "pneumo-typhoid" to those in which consolidation of the lung is present at the onset. Von Stühlern[54] succeeded in isolating the typhoid bacillus from the sputum of three patients. Horton-Smith[53] in the Goulstonian Lectures doubts the existence of such a condition. In his opinion the pneumococcus is also present and must therefore be regarded as the exciting cause; where it is not present its absence is due to the lateness of the examination when the coccus has disappeared. J. W. Smith[58] who had an enormous number of cases of enteric fever under observation during the South African War found both catarrhal and croupous pneumonia to be very rare and this in spite of the fact that the men were treated in tents.

Five instances of typhoid fever complicated by diphtheria are reported by Morris Manges[127]. Neither the membrane nor the antitoxin seemed to have any influence on the typhoid fever. He also reports one case in which the diphtheritic infection was implanted on Bouveret's ulcers.

These ulcers, first described by Bouveret in 1876 are symmetrically placed on the fauces, are oval in shape the long axis being parallel with the tonsil. They are surrounded by a reddish halo and have a greyish red or yellow base which is usually smooth.

Bronchitis is so commonly present that it may be said to be a symptom. It may exist from the beginning or appear during the course of the disease. In a series of 129 cases reported by Gillies[46] bronchitis existed at the beginning in 18.5 per cent., and developed during the course of the disease in 11.6 per cent.

Among the respiratory symptoms noted by Billet[128] in 152 cases bronchitis occurred in 55 and laryngitis in 15.

Congestion at the bases of the lungs is as a rule a late manifestation due to enfeeblement of the heart. Pulmonary infarcts with resulting pleurisy are among the rare complications. This subject is considered more at length under the head of typhoidal pleurisy.

Typhoid Pleurisy.—In a previous essay by one of the writers the statement was made that pleurisy was an extremely rare complication of typhoid fever and that when present was due to an infarct, gangrene or abscess. Several writers since then have made the same statement in re-

porting pleurisy occurring as a complication. While it is undoubtedly not very common, still pleurisy complicating typhoid fever cannot now be said to be rare and furthermore many cases recently reported indicate that it may arise independently of a gross lesion in the lung. It is not usually met with during the early stages but develops as a rule about the third week. If effusion takes place it is quite apt to be hemorrhagic or purulent in character. It is held by many that pleurisies occurring as a complication to typhoid fever are set up by the Eberth bacillus and that that germ may be demonstrated in the fluid. The term pleuro-typhoid is applied to those cases in which the onset of the typhoid is coincident with an acute pleurisy due to the bacillus typhosus. Osler in *Studies No. II.* has reported a case of this kind. Two recent cases are reported from Dr. Chauffard's[59] clinic with an acute onset manifested by pain in the side and a rapidly forming effusion. On aspiration a hemorrhagic fluid was obtained containing an abundance of the typhoid bacillus. Labiche[60] was able to collect but 10 cases showing the bacilli from the literature. Gordinier and Lartigau[61] have also recorded a case in which removal of a hemorrhagic effusion gave a pure culture of the typhoid bacillus. Two cases of hemorrhagic pleurisy due to Eberth's bacillus are reported by Longuet[129]. Horton Smith,[53] in opposition to these views, raises the same objection to pleuro-typhoid that he does to pneumo-typhoid and is inclined to doubt its existence.

Remlinger[130] states that pleuro-typhoid may occur as the first symptoms of typhoid fever; as a complication late in the disease; that it may rarely occur not as a result of the Eberth bacillus but of some secondary infection; and still more rarely it may arise in the terminal stages of acute phthisis with no signs of typhoid fever at autopsy. Of this latter group two cases have been reported.

Instances of pleurisy following a pulmonary infarction are reported by Galliard[62] and Rothe.[27] In each instance the onset occurred during the third or fourth week, was sudden and was attended by pain and bloody expectoration. Widal and Merklen in six months observed no less than ten cases of pleurisy complicating typhoid fever. Three of the cases are reported in detail, all showing the presence of the typhoid bacillus in the effusion which in ten of the cases was hemorrhagic. Gillies[56] in 129 cases observed pleurisy in seven instances, 4 developing an effusion. Osler in *Studies No. III.* states that simple fibrinous pleurisy is the most common form. It appears in the side or at the base and is not followed by effusion. In seven cases a dry pleurisy was marked while in nine a more positive friction rub was demonstrable. He had one case in the last series which developed a purulent effusion during convalescence. Cultures from this effusion gave a pure growth of the bacillus typhosus. Remlinger[48] found that among 315 cases death has been caused in five instances by pleurisy with effusion. In three instances the effusion was hemorrhagic, one purulent and one serous.

Temperature in the Well-Developed Stage.—Hypothermia, according to Osler, is a condition which is very common in two diseases, namely: malaria and typhoid fever. Persistent subnormal temperature has been occasionally observed throughout the course of typhoid; the first two instances being recently reported, one by George Boody,[41] the other by Larquier,[63] and a third by Etienne[131]. Three instances were insane patients. Just as croupous pneumonia with overwhelming toxemia is often attended by a low temperature, so may the septicemic typhoid have a temperature which never goes above 101.5° F., although as a rule hyperpyrexia is common in this condition. Sudden and decided drops in temperature are of frequent occurrence in typhoid fever. They may occur spontaneously during the period of remission during the third or fourth week, as an indication of hemorrhage and as an indication of perforation with impending peritonitis. Then, too, they occur as an effect of the tub bath. It must be borne in mind that in a certain porportion of cases the temperature rises instead of drops with hemorrhage. In children, the temperature instead of conforming to the type of that of the adult is apt to be remittent in character. Blackader[73] found this to be the prevailing type of temperature in the majority of 100 cases analyzed by him. A. Billet[132] in reporting 152 cases occurring in soldiers states that 111 were severe and of these 75 per cent. had hyperpyrexia.

Hyperpyrexia as a rule occurs in the septicemic type of the disease. The temperature may become astonishingly high, reaching 108° F., as in a case reported by H. G. Turney,[64] or it may remain persistently high (104°-105°) for weeks. In two cases reported by de Grandmaison,[3] the temperature was not only high but markedly irregular. Sudden rises of the temperature during the course of the disease usually indicate some secondary infection or infection of some other organ by the typhoid bacillus, as the lung, pleura or gall-bladder. The febrile temperature may extend over an extraordinary long period of time, thus Murrell[65] reports a case in which the temperature lasted for 81 days. H. E. Belcher also cites a case in which 105 days elapsed before the temperature finally became normal. In this instance, however, there were two relapses. Hawkins and Thurston[133] report a girl aged eleven years who had fever for one hundred and fourteen days. This case was prolonged by perforation, with operative recovery, on the forty-first day and subsequently by a parotid abscess and otitis media.

It would seem that exceptionally high degrees of fever are of serious significance and generally indicate severe toxic symptoms. On the other hand, as has been pointed out, a low fever with evidences of marked infection is of even graver significance. Anything which markedly alters the course of the fever either as a rise or a drop,

is of serious significance as it almost invariably means some complication.

Skin in the Well-Developed Stage.—Aside from the typical rose rash of typhoid numerous instances of variations from the ordinary type and other cutaneous disturbances are being constantly reported. Osler in *Studies No. III.* noted 18 cases in which the rash was petechial from the start, or the rose spots during the course of the disease became petechial in character. In 93 cases he observed the rash in other regions than the chest, back and abdomen. Melville,[134] recording 295 cases, states that in 40 per cent. there was no eruption, while in 20 per cent. the eruption was profuse, extending over the extremities. Of the disturbances occurring with the greatest frequency we must consider boils as probably the most frequent skin lesion although their tendency is to appear during convalescence rather than during the height of the disease. Busquet[66] reports a case in which boils first appeared on the twenty-fourth day and in the course of a few days spread all over the body. Pus from the boils gave a pure culture of typhoid bacilli.

Herpes labialis has been looked upon as exceedingly rare in typhoid. Inasmuch as the condition usually occurs at the onset, the possibility of malaria is always suspected. Osler[47] makes the statement that herpes was noted in 29 cases out of his 829 cases, and probably occurred in a great many more. Rose and morbilliform rashes are by no means rare and seem to occur with greatest frequency in children as is shown in what we have to say about children suffering from typhoid fever. Weill and Lesieur[16] describe a class of cases occurring among children in which the eruption in six was exanthematic in character. Erythematous rashes of various types have been reported by different observers, appearing as a rule in the later stages of the disease. Desquamation quite often occurs as these rashes fade. Remlinger[48] observed six cases of severe infection in which an erythematous rash occurred during the decline of the fever and in all of which desquamating scales were intermediate between those seen in scarlet fever and measles, and occurred for the most part on the lateral aspects of the chest and abdomen. Remlinger inclines to the view that the desquamation is the result of trophic disturbance and is analogous to alopecia. Remlinger[48] has also described another type of eruption of which he records 12 cases, all soldiers, and has collected 40 other cases. This rash is erythematous in character and may exist in two forms; one a scarlatiniform or a rubeolo-scarlatiniform erythema. The first is rare and of very serious significance. It may appear during the fastigium of hypertoxic cases preceding death by but a day or so; or it may appear during the convalescence of cases of moderate severity. In this type desquamation takes place before the eruption fades and death is apt to follow from cachexia or convulsions.

The rubeoloform eruption is much the most frequent, occurring in 31 of the cases collected, while in 14 it was mixed, and in but 4 was the eruption purely scarlatiniform. This rubeoloform eruption may also occur either at the fastigium or during convalescence. When it occurs at the fastigium it is accompanied by a rise in temperature, vomiting and diarrhea, and gives the impression that a secondary infection has taken place. It is most abundant on the extremities, especially about the flexures; the face is also involved while the body is but slightly affected. It is transient in character and has not the grave significance of the scarlatiniform rash although it sometimes precedes death and to a certain degree announces the approach of death. When this form occurs during defervescence, it is occasionally accompanied by a slight rise in temperature, which is brief and fades as the eruption fades. This form is benign and favorable.

J. M. DaCosta[67] in writing on this same subject takes a contrary opinion to that of Remlinger. He states that the scarlatiniform erythema does not necessarily give an unfavorable prognosis; that it is not followed by desquamation, and that it is not followed by albuminuria. In his opinion the rubeoloform rash offers greater difficulties in diagnosis, and it is sometimes almost impossible to differentiate it from true typhus fever, or to be absolutely sure a concurrent attack of measles is not present. He was compelled in one instance to isolate a case for fear of typhus fever. As a rule this rash can be told from measles by the absence of catarrhal symptoms, crescentic arrangement, coarseness, and shotty feel of the latter. In DaCosta's opinion these rashes are of nervous origin the result of irritation by infecting material. He did not believe that they had any prognostic significance whatever. Engelbach[68] records a case with a general scarlatiniform and rubeoloform eruption. The case had a complicating pericarditis. He states that he has seen similar cases and believes them all to be due to secondary inflammations.

In the later stages of the disease sudamina and miliary eruptions are of frequent occurrence due to sweating. Sudamina in the inguinal region occurring as an early manifestation has been observed by Vinke.[69]

In the previous essay on typhoid fever reference is made to a type of typhoid fever described by Jacod[70] and called by him sudoral typhoid fever. He has recently reported more cases of this variety but does not go into detail as to the particular cases. Among the unusual eruptions noted in the Johns Hopkins Hospital may be mentioned urticaria, pemphigus, ecthyma and a papular rash. Erysipelas, a rather unusual complication during the height of the disease was noted in three instances by J. W. Smith.[58] One of his cases developed a second attack of the disease. Remlinger[57] in an investigation as to the cause of death in 315 cases noted erysipelas in one instance. In a group of 152 cases Billet[135] noted erysipelas in 3 instances.

Purpura has always been regarded as an extremely rare occurrence in typhoid fever but during the past two years no less than 17 cases have been reported. Nichols and Learmonth[71] in reporting a case have made a thorough analysis of the reported instances of hemorrhagic typhoid fever. Owing to the obscurity of these cases the writers have suggested that the name hemorrhagic diathesis be applied to this condition. The purpuric manifestations are not ushered in by any special chain of symptoms. The hemorrhage is not sudden but consists of oozing from the mucous surfaces and the appearances of petechial or ecchymotic eruptions on the skin. Epistaxis alone is not to be considered as constituting the purpuric condition. As a result of the bleeding a grave and severe form of secondary anemia often results. Nénoff[72] in a study of 11 cases states that a severe typhoid infection alone or an associated secondary infection is capable of producing the condition. The prognosis in this class of cases is extremely grave. Blumer[6] has reported the case of a child which is of extreme interest from two points of view: first, the infection occurred in utero; second, shortly after birth the child manifested purpuric symptoms, bleeding from the nose, gums and vagina. Death occurred on the ninth day.

The Genito-Urinary System in the Well-Developed Stage.—Albumin in the urine during the attack of typhoid fever while it may be the result of an acute nephritis, is more usually a result of the eliminations of the toxins. In other words, a febrile albuminuria. It would seem that the exanthematic type occurring in children described by Weill and Lesieur[16] is more apt to be associated with albuminuria. In 58 cases they noted its presence in 25, while in 100 cases reported by Blackader,[73] slight albuminuria was noticed but 5 times. Gillies[46] found acute nephritis developing during the course of the disease in 4 cases out of 86. Blocker[74] reports a case with slight hematuria in the third week associated with a large amount of albumin and casts. Several days later an ulcerative endocarditis was made out. It is highly probable in this case that the acute nephritis was set up by an infarct. As was pointed out in the section on hemorrhagic typhoid fever, bleeding from the kidney may manifest itself as a part of a general purpuric manifestation. Young states that while from 20 to 40 per cent. of all cases of typhoid fever show evidences of a bacilluria during the acute or convalescent stage, but very few have pyuria or definite signs of a cystitis. Cystitis, the result of systemic infection by the typhoid bacilli, is found as a rule as one of the after-effects of the disease.

Orchitis and epididymitis while occasionally arising during the course of the disease, occur more particularly during the convalescent stage and will be spoken of later. It should always be borne in mind that during the height of the disease retention of urine is quite as apt to occur as incontinence. For this reason the bladder should be carefully examined at each visit. One should not be thrown off his guard by the dribbling of retention.

An extremely rare complication is reported by Musser[75] and Kelly, that of hemoglobinuria. The presence of hemoglobin in the urine lasted for seven days and the case ended in complete recovery. Remlinger[57] also reports a case of hemoglobinuria. In his case hemoglobinuria associated with severe icterus appeared the day of death. Osler's[47] statistics show strikingly the extent of febrile albuminuria in typhoid fever—75 per cent. of 829 cases. Tube casts, granular and hyaline occurred in 68 per cent. With the appearance of large amounts of albumin, blood and epithelial casts the condition must be considered one of acute nephritis. Osler states that this nephritis is peculiar in that it is not associated with dropsy, and that it invariably clears up. The presence of albumin and a few hyaline or granular casts need cause but little concern.

Nervous System in Well-Developed Disease.—The headache which is present during the prodromal stage and first week of the disease as a rule disappears and is replaced by delirium of the low muttering type, or it may be active and noisy. Active and violent delirium may appear suddenly and without warning as in a case reported by W. B. French.[15] The patient was suddenly seized on the twenty-fifth day, as fever was declining, with violent delirium and suffered a relapse. Restlessness in sleep or insomnia is not of infrequent occurrence during the second and third weeks. The headache, however, may be persistent and aggravated throughout the attack. Inflammation of the nerves during the height of the disease is extremely rare; the condition coming on as a rule during the period of convalescence. It would seem from a review of the cases occurring in the well-developed stage of the disease that neuritis is localized rather than general,[76] and is more apt to affect the nerves associated with the eye. Braun has seen three cases in two of which the right abducens was involved and in the third the paralysis was bilateral. In a fourth case there was optic neuritis. Polyneuritis was observed by Garniez[77] once, the condition developing on the fifteenth day. He was able to find but fourteen cases in the literature. In a research of the literature Dufour[136] found three cases of catalepsy. All three occurred in young women free from hysteria and neurotic history. In each instance the cataleptic attitudes were assumed between the seventeenth and twenty-first days. Dufour uses the term catalepto-catatonic to designate the cataleptic attitudes, with stupor, a symptom of severe typhoid fever.

Convulsions occasionally develop, as a rule without any ascertainable cause and rarely as an indication of hemiplegia.[47] As was pointed out in the section on the arterial system hemiplegia is almost invariably the result of embolism, thrombosis or hemorrhage. This condition is by

no means usual. Four cases have been recently reported, three by Osler[47] and one by Auden;[7] the latter's case developed as early as the eighth day with a convulsive seizure. While aphasia often exists as a part of a hemiplegic condition it sometimes arises without the presence of any organic lesion to account for it. It has been noted in a previous essay by one of the authors that simple aphasia usually occurs in children. Such was the case in two recently reported cases by Da Costa[79] and Samuels.[20] Billet[137], however, met with six cases of aphasia among 152 soldiers suffering from typhoid fever.

Among the unusual complications may be mentioned a case of bulbar paralysis of sudden development (Laborde);[80] three cases of tetany (Janeway)[17] and acute ascending hemorrhagic myelitis arising on the ninth day with death in 18 hours (Schiff).[81]

The reflexes during the course of typhoid fever have been investigated by Remlinger[82] in a study of 100 cases. In 29 cases the reflexes were absent, in 22 were normal, in 17 diminished, and in 32 they were exaggerated. Ankle clonus was detected in 21 cases; patellar clonus in 8; and the contra-lateral reflex twice. He concluded that there was no constant relation between the state of the deep reflexes and the gravity of the patient's condition. But in severe infections the reflexes tend to become exaggerated and that abolition of the deep reflexes is to a certain extent a favorable prognostic sign.

The Alimentary Canal in the Well-Developed Stage.—A rare manifestation is reported by Barksdale,[28] that of gangrenous stomatitis involving the left cheek of a mulatto child during the second week. A few days later the opposite cheek was attacked, causing death by exhaustion. Parotitis is not a usual complication occurring in but 1.4 per cent. of a large series (829) reported by Osler.[47] In two of his recently reported cases the sublingual glands were involved and in another a double parotitis occurred preceding an orchitis. Among 86 cases reported by Gillies,[46] parotitis occurred but once. The condition usually develops during the third week and occasionally as early as the second week.

Glossitis is a very rare complication. Thompson[44] reports a woman who suddenly, during the fourth week, developed a firm, non-fluctuating and tender swelling on the left side of the tongue. In a short time the right side became swollen. Several small ulcers were found in the dorsum of tongue, but no suppuration occurred. Ulceration of the fauces and palate has been described several times during the last few years. Schaefer[83] believes that ulceration at these points exists in fully 20 per cent. of all cases. In the great majority of cases there is no pain or discomfort. Hence the throat is never examined. While a deep form of ulceration has been described before, Schaefer asserts that the existence of a superficial variety has never been adequately recorded. In most cases the superficial ulcers appear during the second week, although they may appear earlier or later. They are symmetrically disposed, being either single or multiple, near the junction of the anterior pillar with the soft palate. The base is grayish yellow, smooth and either punched out in appearance or surrounded by a zone of hyperemia. Attention is usually called to them by some pain and tingling.

Two remarkable cases of stricture of the esophagus are recorded by W. C. Dugan[84] occuring in a house epidemic in which the mother and three sons were successively stricken with the disease. The mother and oldest son died. During convalescence, one of the survivors complained of pain in the chest and difficulty in swallowing. A few weeks from the first evidence of this trouble there was complete obstruction to a bougie. This patient died. In the survivor no trouble arose for two or three years when he developed complete obstruction of the esophagus and was operated on with a good result. Two additional cases have been reported, one by Mitchell,[47] the other by Summers.[55]

Occasional vomiting occurs during the course of typhoid, but as a rule it is uncommon. Vomiting of blood as a part of a hemorrhagic condition is seen at times and in rare instances is independent of any such condition, as in a case reported by Osler.[47] Meteorism is a common manifestation in adults, occurring in 20 per cent. of 129 cases by Gillies.[56] It is looked upon as an indication of rather deep ulceration. In this connection it may be said that, according to Stowell,[9] meteorism is not usual in children. It is well known that in the very young perforations and hemorrhage are not common. All reports on typhoidal fever at the present time indicate that the profuse diarrhea of several decades ago has disappeared and that constipation is quite frequently if not more commonly met with.

Perforation, that most dreaded of all the complications of typhoid fever, is most commonly seen in the third week, although it may occur as early as the second, or as late as the fortieth day. Finney[47] has examined a large number of statistics which show that perforation occurs in between 1 and 2 per cent. of all cases. Perforation is the cause of 10 per cent. of all deaths. F. W. Smith found perforation of very common occurrence, taking place in nearly one-third of all fatal cases under his care. The most usual site is within the last 24 inches of the ileum, occasionally in the large intestine, and still more rarely in the appendix. The perforation is usually single, but may take place in two or more places. Celos[86] has seen a case in which perforation occured twice in the transverse colon. During the past few years there has been a decided tendency towards surgical interference in cases of perforation with the result that many cases heretofore inevitably doomed to death have been saved. From a purely medical standpoint the most important of recent contributions on this subject is by Osler.[87] He states that we must change our views of perforation very materially.

What have hitherto been looked upon as symptoms of perforation are pain, limitation of the respiratory movements of the abdomen, extension of liver flatness, presence of blood or sloughs in the stools, pallor, drop in temperature, hiccough and a stationary or rising leucocytosis. Osler does not believe that the so-called preperforative stage of Cushing is of much value. Perforation may be caused by external trauma as in a case reported by Andre.[58] A man suffering from ambulant typhoid was kicked in the abdomen by a horse. Apparently there were no ill effects from the kick itself, but five days later perforation and death occurred, presumably from the trauma received. The fact that no post-mortem was held throws doubt upon the idea that this was the real cause of death. Remlinger[57] found three perforations in four cases and four perforations in two others. Death from perforation in the majority of cases occurs between the twentieth and twenty-fifth day.

The most frequent time of hemorrhage is during the second or third week although Remlinger found in investigating a large number of cases that death most often occurred, as a result of the accident, between the twenty-fifth and twenty-eighth day. Hemorrhage while decidedly more frequent than perforation is far from being so fatal. While nearly every case of perforation will probably die without operation, the great majority of those having hemorrhage recover. If we compare the results in large numbers of cases we can arrive at conclusions as to the relative frequency of these two accidents. Thus among 829 cases in the Johns Hopkins Hospital there were 50 cases with hemorrhage and 23 with perforations; in 215 cases reported by Gillies[46 56] during the past two years, perforation occurred six times, hemorrhage 21 times. On the other hand, in some epidemics the number of perforations are the more numerous; this was the experience of J. W. Smith.[58] Hemorrhage may occur but once or may recur at intervals, and while usually unattended by perforation, it sometimes precedes that condition. It is generally spontaneous but may follow enemata; ten such cases are recorded by Osler in *Studies No. III.* A sudden drop in temperature and rapidity of the pulse rate are looked upon as strongly indicative of hemorrhage but the pulse may remain unchanged. Among 23 cases recorded by Osler, in six the temperature remained unchanged. An unusual source of hemorrhage is reported by S. G. Longworth[138]. A woman died as the result of three profuse intestinal hemorrhages. At autopsy the source of the hemorrhages was found to be the sigmoid flexure which presented a hemorrhagic and infiltrated appearance. Hemorrhage from the bowel during the course of typhoid, as a rule, means but one thing; occasionally, however, enterrhagia may occur, the result of a purpuric tendency. When it does it is usually associated with bleeding from some of the other mucous surfaces. Instances of this kind are reported by Gillies[56] and Pinard.[18] Hemorrhage in children is of rare occurence, and the younger the child the less liability is there to this accident. Blackader[10] in a series of 100 cases and Barbier[12] in a series of 47 cases make no mention of this accident having occurred. Stowell[9] observed hemorrhage in three cases, two at twelve years and one at fifteen.

Typhoid Without Intestinal Lesions.—This is a subject that has recently been attracting considerable attention. Flexner[47] has reviewed the literature and collected some twenty cases in which individuals showed every evidence of typhoid fever, and yet at post-mortem no intestinal lesions were found. Unless this fact is borne in mind the pathologist can readily overlook the true condition. Such cases require bacteriological investigation to definitely determine the truth of a diagnosis. Flexner believes that in these cases, just as in ordinary typhoid fever, the infection takes place through the intestinal tract. He points out the well-known fact that the tubercle bacilli pass through a mucous membrane and invade the adjacent lymphatic gland without leaving any lesion in the mucous membrane. In view of this fact it is perfectly reasonable to suppose the same thing may be true of the bacillus typhosis. Picchi[89] reports two cases of typhoid occurring in a house epidemic without the characteristic lesion but is inclined to reject fourteen of them for lack of conclusive evidence. He takes the same view as Flexner, that the primary invasion is through the intestinal tract. Ophüls[90] adds a case in which a complete bacteriological examination showed undoubted typhoid in the absence of intestinal lesions. A remarkably interesting case is reported by Opie[91] of a child, ten years of age, who in addition to the ordinary manifestations of typhoid had marked purpuric symptoms including bleeding from the bowel. The intestinal bleeding was supposed to be from the ordinary source and yet post-mortem examination revealed no ulceration. The Peyer's patches and solitary follicles were slightly swollen and pigmented. The bleeding was thought to come from the stomach which showed numerous ecchymotic areas.

Circulation in the Well-Developed Stage.—Gradual weakening of the first sound and increased rapidity of the heart's action occurs in practically all cases of typhoid in which the infection is at all severe. Guyard[20] in a study of typhoid myocarditis states that even where the condition cannot be demonstrated clinically that myocardial degeneration can be known to exist histologically as a rule, in all fatal cases. Typhoid myocarditis manifests itself by a sudden oppression, cyanosis, dyspnea, tachycardia and fetal rhythm. Guyard, however, believes that weakening of the first sound and pulse rate of over 100 justifies one in making the diagnosis. In a study of the causes of sudden death in typhoid fever Remlinger[57] attributed it to cardiac lesions in 11 out of 38 cases. Involvement of the endocardium and pericardium is extremely rare;

thus Horton Smith[53] found but two cases of endocarditis and ten of pericarditis in an analysis of the autopsy records of St. Bartholomew's Hospital for the past thirty years. The endocarditis is usually malignant and may be the result of a secondary infection or be caused by the typhoid bacillus.

In the previous essay by one of the authors mention was made of a form of typhoid described by Bernheim and designated "forme cardiaque," the chief signs of which are asystole, feebleness and tachycardia. Bernheim was of the opinion that the condition was due to some derangement of the cardiac nerves rather than an affection of the myocardium. Gabbi[28] reports a case of this kind which was also complicated by hysteria.

Involvement of the arteries is far more rare than disease of the veins. It is highly probable that the arterial damage is due to direct bacterial infection which favors thrombosis with a resulting hemiplegia or still more frequently gangrene. The gangrene usually involves one or both of the lower extremities. Of 13 cases of arteritis recently reported gangrene of the lower extremities occurred in 8. J. W. Smith[97] observed 6 cases of gangrene in the South African Hospitals. Phlebitis is undoubtedly the most common lesion of the vascular system and as a rule is of no serious consequence. J. W. Smith states that it occurred very frequently among the soldiers under his care in South Africa, but never led to any untoward event. Occasionally, however, an infarct may take place in the lung or even more serious damage may result as in a case reported by Dettling and Remlinger[92] where pneumothorax resulted. The veins most commonly affected are the femorals and it is well known that the left is more commonly affected than the right. The iliac, saphenous and brachial veins have also been reported as involved.

As the result of the secondary anemia developing during the course of the disease functional disturbances are frequent during the later stages. A hemic murmur heard either at the apex or base of the heart and a soft compressible pulse are often noted. It would seem that these murmurs are more frequent in children than adults as Blackader[73] noted them in 22 out of 100 cases and Barbier and Herrenschmidt[12] in a third of 47 cases, while Gillies[56] among 129 adults observed them in but 11 cases.

The Blood During the Well-Developed Stage.—Thayer,[47] in a study of 829 cases occurring in the Johns Hopkins Hospital during the past eleven years clearly shows the gradually progressive secondary anemia which occurs as the disease progresses; the existence of leucopenia, and the presence of a leucocytosis in complications such as abscess, phlebitis or peritonitis. In a study of the different counts it was found that the mononuclear cells were increased while the polymorphonuclear cells and cosinophiles were reduced. While leucocytosis was present after hemorrhage it was of no value in anticipating the condition. The most notable and important fact connected with the blood is the progressively increasing number of the colorless cells following perforation. In this connection it must be borne in mind that the number of white cells in typhoid fever is reduced so that a count of 8,000 per cubic millimeter is often of grave significance. Osler,[93] Finney and Cushing[47] in recent articles call attention to the importance of making hourly estimates of the white cells in cases of suspected perforation. If the white cells show an increase from hour to hour operation should be performed at once, but preperforative leucocytosis so called cannot be relied upon. C. R. Russell[139] in a study of leucocytosis in perforation comes to the following conclusions: leucocytosis is the general rule but varies and may be delayed until peritonitis sets in or may be entirely absent. Leucocytosis may be present and perforation absent. With distinct leucocytosis even in the absence of sings of perforation operation is justifiable. Morse[140] believes that owing to the diminished number of leucocytes in typhoid fever the presence of leucocytosis should make one wary of making a diagnosis. He also states that careful watch of the leucocyte count enables the physician to anticipate complications.

The presence of the typhoid bacillus in the blood has been demonstrated in a number of cases after death, but as yet very few cases are on record in which they have been found during life although recently excellent researches have been carried out by American investigators whose papers are still unpublished. Horton Smith[53] believes that with improvement of technic it will be possible to show their presence in all cases during life. He is inclined to believe that the bacilli always gain access to the blood stream, but are rapidly deposited in various organs or are destroyed as the blood is a bad medium for their existence. De Grandmaison[8] succeeded in obtaining the organisms in pure culture from two cases of septicemic typhoid fever.

The value of the Widal reaction is so well established that little need be said concerning it. In all recent reports covering large numbers of cases it has been present in from 98 to 99 per cent. Making the Widal test as a routine practice is well illustrated by Libmann,[141] who cites a number of cases in which from the history typhoid fever was unsuspected until a positive reaction was reported, yellow and degenerated. Morse[7] in a study of fetal and infantile typhoid fever found that the reaction occurred in infantile forms of typhoid fever as well as in the adult. In these cases the agglutinating power is either transmitted from the mother to the child through the placenta or it may be formed in the child in response to toxins transmitted from the mother.

(To be concluded.)

MEDICAL PROGRESS.

The Hair in Typhoid Fever.—H. M. LITTLE (*Montreal Med. Journ.*, May, 1901) has examined sixty-two cases some months after their typhoid, and noted the results as follows: Thirty-five had their hair cut in the hospital, and in only seven did the hair subsequently fall out. Of these seven, four were cut late. The ultimate result in all was a thicker growth of hair than ever before, and in two cases it was thought to be coarser. Twenty-seven did not have the hair cut, and in only three was there no falling out. Ten had to have the hair cut later to prevent baldness. In seven other cases not cut, four are very thin, two still falling, and one, before curly, is now thin and straight.

Typhoid Perforation and Leucocytosis.—C. K. RUSSEL (*Montreal Med. Journ.*, May, 1901) draws the following conclusions from cases observed: In perforation it is the rule to have a leucocytosis, but the degree may vary within wide limits. The leucocytes, though generally appearing early, may not be at all marked until the general peritonitis and collapse have supervened. There may be an utter absence of leucocytosis with marked perforation and peritonitis—in fact, the white cells may be lower than normal. With typical signs of perforation and a definite leucocytosis, there may be no perforation and an operation may be performed unnecessarily. A marked leucocytosis may occur in complications other than perforation, as bronchitis, cholecystitis, otitis, etc. With pain and tenderness in the abdomen, coming on suddenly during an attack of typhoid fever, and in the absence of evidence of other complication, a distinct leucocytosis even without other signs of perforation, justifies an exploratory operation, for if there is perforation delay is fatal.

The Widal Reaction.—From time to time doubts are expressed as to the diagnostic function of this test, and authoritative statements are made depreciating its value. At the Johns Hopkins Hospital, of cases certainly typhoid, 99.6 per cent. gave a positive reaction, and at the Royal Victoria Hospital, the reaction was present in all but one of 151 cases. To ensure success, H. M. LITTLE (*Montreal Med. Jour.*, May, 1901) has found that the cultures require constant care and the most favorable conditions for bacteriological work. The proper preparation of the culture is the greatest of all difficulties; it should be acid, preferably exactly 1.5 per cent., for with alkaline media the bacilli may clump spontaneously. The author has always used a double control, and has taken as his standard for the reaction, *clumping with relative slowing of bacilli.* Of interest are the statistics of the author of cases which gave reactions in the hospital during the previous three and one-half years, 75 of which were looked up by him and re-examined. Of 42 cases tested within a year of the disease, 24 were positive with average age of twenty-five years, and 18 negative averaging sixteen years; of 13 cases within two years of the disease, 5 positive averaging twenty-nine years, 8 negative averaging twenty-two and one half years; of 11 cases within three years of the attack, 5 positive averaging twenty-one years, and 6 negative averaging twenty-five and one-half years; of 9 cases within three and one-half years, 3 positive averaging forty years, and 6 negative averaging thirty-one years. No definite data seem obtainable whereby one can associate the duration of the reaction with any special feature of the disease. Of interest is the not unusual absence of the reaction in late stages of the uncomplicated cases, when we are assured that living bacilli must still be present in the tissues.

Colon Bacillus as a Cause of Diphtheria.—SEITZ (*La Méd. Moderne*, May 22, 1901) describes a case in which three days after chill and fever with symptoms of angina, a false membrane appeared on the right tonsil. Antitoxin was administered and bacteriological examination ordered. The patient promptly died in collapse. Examination of the membrane by microscope and culture revealed nothing but colon bacilli. The case was evidently one of diphtheroidal affection of the throat due to the colon bacillus, and is analogous to pseudo-membranous inflammation of the intestine due to the same cause.

Phosphergot as a Tonic.—Luton (*Jour. de Méd. de Paris,* May 26, 1901) recommends for its value as a tonic a "phosphate of soda and of ergot." Its results have been favorable in melancholia, hysteria, adynamia, and chlorosis. It overcomes the great constitutional depression of the algid stage of certain fevers. Sodium phosphate alone has been employed heretofore in the cerebral torpor of senility, but the combination with ergot increases its efficacy. The general indication for the administration of "phosphergot" is functional debility of nervous origin.

Surgery of the Pancreas.—Mayo Robson (*Prager med. Wochenschr.,* May 16, 1901) reports forty cases of operation for pancreatic disease. Inflammation may confine itself to the pancreatic duct, or may be interstitial and chronic. The acute forms are manifestations of infection. Chronic pancreatitis is often mistaken for carcinoma, which on cut section it macroscopically resembles. Where chronic inflammation originates in the duct it is invariably an accompaniment of gall-stones. Cases in which there occur jaundice, weakness, emaciation, paroxysms of pain and fever, and which cannot be relieved by medication, demand surgical interference. Ceccherelli points out the advisability, in purulent or gangrenous pancreatitis, of postponing operation until the subsidence of the acute period. In operating, three routes offer themselves, namely, the lumbar extraperitoneal, the transpleural, and the median subumbilical.

Effect of Football Training on the Heart.—E. A. Darling (*Boston Med. and Surg. Jour.,* June 6, 1901) made routine examination of seventeen members of the Harvard football squad. Fourteen of the men showed no disturbance of cardiac action, although in all there was some hypertrophy. In two cases temporary murmurs were detected, and in one instance only was there evidence of a slight organic lesion of the mitral valve. The last case showed irregularity of rhythm after two weeks of hard practice, but three months after the close of the season the pulse was 76, regular and normal. Examinations after a hard game showed increased area of dulness, increased pulse-rate up to 150, roughened first sound at apex and very often a faint blowing systolic pulmonic murmur. In vigorous hearts these signs were of very brief duration. While permanent hypertrophy results from long periods of training, Dr. Darling does not consider this any more undesirable than a corresponding hypertrophy of the biceps muscle.

Surgical Treatment of Active Gastric Ulcer.—Surgical interference is demanded, according to F. B. Lund (*Boston Med. and Surg. Jour.,* June 6, 1901), in all cases of perforation. Where the symptoms do not yield to medical treatment after a reasonable period, excision of the ulcer or gastro-enterostomy should be performed; operation should not be delayed until the exhaustion of the patient renders surgical intervention dangerous. Early operation is advisable where frequent bleeding, even if slight, threatens to produce anemia or exhaustion. Copious hemorrhage if repeated calls for active interference.

Thiocol in Pulmonary Tuberculosis.—The influence of thiocol has been carefully studied by Maramaldi (*Gaz. internat. di med. pratica,* No. 8) who finds that it causes marked amelioration of the symptoms of pulmonary tuberculosis. In cases not too far advanced temperature is reduced to normal, the cough becomes less severe, the sputa are reduced in quantity, the number of bacilli is diminished, the patient's appetite improves, and there is a gain in weight and strength. While these changes are noticed in the early stages of the disease, they are not obtained in the stage of cavity formation. Thiocol is given in divided doses aggregating 1 to 3 grams daily. Such doses control diarrheal manifestations and night-sweats almost invariably. As an adjuvant to hygienic and dietetic treatment, the drug is recommended in the class of cases referred to.

THERAPEUTIC HINTS.

Blenorrhea Neonatorum.—The dropping of a solution of nitrate of silver into the eyes is too severe for routine practice, but may be resorted to where infection is positive. Protargol, the application of which should always be preceded by thorough cleansing, is more penetrating, less caustic, and quite as efficient. During the first or catarrhal stage, C. D. Westcott and B. Pusey (*Amer. Jour. of Nursing,* June, 1901) use iced compresses for one hour twice a day, gentle flushing with warm boric-acid solution or 1-2,000 permanganate of potash, and the daily application of ten-per-cent. protargol. Silver nitrate and mercuric bichloride are best omitted as too irritating. When pus forms, the eyes should be cleansed frequently, and the lids anointed with sterile vaseline to prevent agglutination and the retention of the discharge. A twenty-per-cent. protargol solution, preceded by boric acid or permanganate, may be dropped in twice daily. At each cleansing, the shreds of mucus should be flushed out of the folds of the conjunctiva, or removed by cotton on the end of a toothpick. The slightest haziness of the cornea, or edema of the ocular conjunctiva demands the removal of the cold compresses and the substitution of hot fomentations, which are removed every night for fifteen minutes in each three hours. Atropine should be dropped in the eye, and an edematous conjunctiva scarified by radial incisions. The general nutrition must be looked after closely, and the baby must not be treated at intervals so frequent as to interfere with its proper rest. The chronic conjunctivitis following acute gonorrheal may be treated with a one-per-cent. solution of protargol or one-half-per-cent. solution of zinc sulphate.

SATURDAY, JUNE 22, 1901.

THE SMALLPOX SITUATION ONCE MORE.

In discussing the statistics of smallpox in this country more than two months ago, we said that there would probably be over 30,000 cases of the disease reported in the United States during the first six months of the present year. Our prophecy has been only too fully verified. At the beginning of June there were 27,200 cases on the list, more than two and one-half times as many as for the first five months of last year. This comparison is all the more startling since the number of cases of smallpox recorded last year was considered to justify the expression that the United States was suffering from a serious epidemic of the disease.

Although it is eminently a cold-weather disease, yet reports of boards of health in many parts of the country have brought the news of fresh invasion of smallpox. There is scarcely a State in the Union that has not suffered severely from the ravages of the disease during the winter just past, and there is practically not a single district that has succeeded in permanently banishing the contagion from its borders.

Fortunately the smallpox has assumed a very mild form during this outbreak, with an average mortality of less than 5 per cent. The disease has been so mild, in fact, that in some places there has been serious question whether the epidemic was genuine smallpox. On the other hand, there are localities in which the disease has raged with all its ancient severity. At the beginning of the year there were districts in Mississippi where the mortality was more than 20 per cent. There have always been, too, in the midst of the milder cases some severe ones that ran an almost typically malignant course and thoroughly justified the diagnosis of smallpox for the whole group of cases.

The discussion on smallpox at the recent meeting of the American Medical Association, an account of which will be found in the present issue of the Medical News, emphasized some interesting points. Not all doubt is at rest as regards the authenticity of certain groups of cases in the present epidemic. The possibility of the existence of a disease standing between variola vera and varicella will scarcely be denied. Medical men recently have come to acknowledge the independence of German measles as a type of disease intermediate to scarlet fever and measles. Even a fourth disease in this group has recently been claimed to exist by certain English observers. Careful clinical investigation of the nosological status of anomalous types of smallpox is eminently desirable. As is always true in medicine, the first observers in this line are more apt to meet with obloquy than encouragement. The original work must for a time be its own reward. Its prosecution is well worth while, however, for the question involved is one of the most important in medicine. Meantime indefinite conclusions and inadequately completed observations must not be allowed to hamper the work of sanitation and vaccination which can alone bring the present epidemic to a close.

The question of the protective power of vaccination is being thoroughly settled by the reports of smallpox received from all over the country. The unvaccinated are suffering almost exclusively. When vaccination does not prove protective there is always some question either of the genuineness of the smallpox that followed or of the authenticity of the vaccination. As the result of recent experience, there is no doubt, however, that the duration of protection after genuine vaccination is eminently individual. It may last for from seven to ten years, but it may run out in a much shorter period. The protection afforded by a previous attack of smallpox also becomes

slight after the lapse of years, so that where an epidemic threatens it is well to attempt the vaccination of all who have not been vaccinated within a few years, even if they bear the marks of the genuine disease.

MAL D'ELEVATEUR.

ONE of the penalties of higher civilization is an increase in the number and variety of diseases to which human beings become susceptible. In the primitive state there is very little use for the physician or the surgeon, even the midwife is usually superfluous. Except in famine, pestilence, or war, those who survive the strain incident to infancy and early childhood have a good chance of weathering the ordinary storms of life and reaching old age.

In our new civilization there are many trades and occupations which give rise to distinctive forms of disease to which the name of the occupation readily attaches itself. Thus we have the caisson disease, the pulmonary disease of grinders, stone-cutters, and all who inhale quantities of dust, the anemia of miners and others who must labor away from the health-giving influences of sunlight. Those who are workers in phosphorus, arsenic, copper, lead, etc., frequently pay a heavy price for the privilege of earning their livelihood through such means, while the occupations in which electricity plays a prominent part have made large contributions to the list of diseases and injuries.

One of the most useful of modern inventions, the elevator, which has become indispensable wherever there are buildings of great height, is destined to play a rather important rôle in the history of disease. The actual results may be slight in some cases, but they are likely to be more severe in others. This is especially true when great speed is required, with sudden starts and stops. However well adjusted the machine or skilful the operator, there is a succession of shocks, and consequent disturbance of the equilibrium of the body. These shocks are much more apparent in downward motion, and the sensation is almost one of pain when there is a sudden drop of two or three stories. Of course, those who are constantly using this method of motion become inured to it in a measure, as the engineer becomes adjusted to the constant rattle and shock of his locomotive. The question is, Will not this repeated commotion of the body, and especially of the movable viscera of the abdomen, produce disease of the organs which are disturbed? We fear it may, and it will be interesting to study the phenomena attending their development.

The sensation or shock which is received in an elevator is not unlike seasickness, especially as it refers to the stomach and, as in seasickness, we may have nausea, vertigo, headache, vomiting, and sometimes heart failure. For those who have weak hearts or stomachs this form of locomotion is not to be recommended. It should enter into the category of forbidden things, so far as may be, for those who are thus affected. The careful and thorough investigation of this subject, both as regards those who ride occasionally, and those who ride constantly, and particularly those who are employed in night work, will prove a fruitful and useful study.

A PSYCHOPHYSICAL LABORATORY AT WASHINGTON.

IF there is ever to be sufficient definite knowledge of living modern civilized man to become of permanent value, it can be gained only by the careful study of large numbers of persons.

It has been proposed and a Senate amendment was introduced at the last session of Congress to establish a psychophysical laboratory at Washington. The purpose of such a laboratory is to collect sociological, pathological and abnormal data, as found especially in children and in the criminal pauper and defective classes, and to make special investigations with instruments of precision.

One of the difficulties of psychophysical work in our universities is that it is confined mainly to small numbers and to a special class of persons, so that it is doubtful whether the conclusions obtained can always be applied to people in general. Such work seems to be more for pedagogical purposes, being done by students desiring to prepare their theses for the doctorate. While many of these theses are very valuable, further investigation along the lines laid down rarely follow. A university could not extend such work to large numbers of individuals, for to compute many and varied data and to tabulate and publish them would involve too much work and expense.

A special and very practical feature would be the study of the criminal and defective classes. Here our Government is most directly concerned,

for millions of dollars are expended in catching, trying and caring for criminals, but almost nothing is spent to study the causes that lead to crime. Thus, in 1890 the expenses of all our penal institutions were more than twelve million dollars; this does not include the cost of criminal and police courts nor of the property stolen nor of the untold injury to the community. A worthless criminal or crank kills a prominent citizen: the injury from such action is often beyond calculation.

We cannot expect to lessen crime or dangerous forms of abnormality unless we study the causes; this is the first requisite in all rational procedure, and these causes should be investigated in the beginning. Special emphasis, therefore, is laid on the investigation of criminal and abnormal *children*. If the world is ever to become better, we must begin with the children. This single phase of the work alone would justify a large appropriation. Our Government gives millions yearly for the study of rocks, plants and animals, but almost nothing for the study of children.

University laboratories have almost wholly ignored sociological conditions, leaving many practical questions untouched. It would be important to know what physical and mental characteristics are common to criminal children and whether such characteristics are due more to the child's nature or to its environment. Thorough and patient study only can determine such questions; theory and speculation cannot do it, although they may accomplish good by calling attention to the matter. It is generally believed, but not yet proved, that crime is mostly due to surroundings. If this can be determined, then there is much hope of lessening crime, for it is much easier to change the surroundings of a child than its nature.

Much study has of late been devoted to children in our public schools; mistakes have doubtless been made by those with more enthusiasm than training, but this is the case with all new lines of inquiry. There are very practical questions concerning our schools; to establish the measure of work according to the strength of the pupil is fundamental to health. This is especially true of children, for overtaxing their powers can leave its mark throughout life. What is the maximum work suitable to a child in the different periods of its growth? Can this maximum be injurious at times when all the vital force may be required for growth? To answer such questions we must know the physiology of normal growth, its rate of increase and decrease and what influences cause them.

It would be desirable to ascertain if there are physical or mental traits in common between unruly children and those in reformatory institutions, between those in feeble-minded institutions and dull children in the schools. Such inquiries, if made with care and discretion, might enable us to foresee the special dangers that this and that child will be subject to and thus make it possible to protect many children from temptations and conditions that might ruin them.

Such investigations should find their place under Government auspices.

ECHOES AND NEWS.

NEW YORK.

Rockefeller Institute Incorporated.—Articles incorporating the Rockefeller Institute for Medical Research, with its principal headquarters in New York, were filed last week with the Secretary of State. It is proposed to promote medical research, with special reference to the prevention and treatment of disease. The directors for the first year are: William H. Welch of Baltimore, T. Mitchell Prudden, C. A. Herter, L. Emmett Holt, and Hermann M. Biggs of New York; Simon Flexner of Philadelphia, and Theobald Smith of Boston.

Enlargement of St. Mary's Hospital.—Plans have been filed with the Building Department for the addition of a three-story and basement annex to the building of the Free Hospital for Children on West Thirty-fourth Street. The extension will be 34 by 50 feet and will be occupied by additional hospital wards and it will also have a handsome chapel. The improvement is to cost $45,000.

Punishments for Adulterating Milk.—Twenty-five milk-dealers, whose arrest was mentioned in a previous number of the MEDICAL NEWS, were arraigned in Special Sessions this week, charged with adulteration of milk. Five pleaded guilty, and were fined, one $50, and the others $25. They were warned that a repetition of the offence would bring them a penitentiary sentence. The other twenty cases were postponed.

Smallpox in the Adirondacks.—The Supervisor of the town of Moriah, Essex County, reported to Dr. Daniel Lewis, State Health Commissioner, that smallpox had broken out in a family in the town, which is situated in the wilds of the Adirondacks, and that it is impossible to get anybody in the town to take the stricken person and the other members of the family to the pesthouse, every one being afraid of contagion. He asked the State Health Com-

missioner for aid. Dr. Lewis authorized him to call on the Sheriff of Essex County for whatever assistance was needed to carry out the law.

Laryngologist to St. Luke's Hospital.—Dr. D. Bryson Delavan has been appointed consulting surgeon, Department of Laryngology, St. Luke's Hospital, New York, in place of Dr. George M. Lefferts, resigned.

Proposed Jewish Hospital in Brooklyn.—A number of prominent Jews who are interested in the movement for the erection of a hospital in Brooklyn met recently and discussed the matter. The Secretary said that he was positive that there would soon be a much larger membership, and he felt sanguine that the new hospital would be erected within a year. At the present time the organization has a dispensary at 70 Johnson Avenue, which is of great benefit to the poor Jewish families of Williamsburg.

Responsibility of a Physician to His Patients.—So rarely is a physician held responsible in damages for either unskilful or unsuccessful treatment of a patient that a recent decision of the New York Appellate Division of the New York Supreme Court, awarding the patient damages against the physician, is in the nature of novel law. In this case a woman, having broken her left arm, was attended the following day by the physician, who put the arm in splints and instructed her to carry it in a sling. After attending her for about six weeks the physician found that the bones had not united. After further treatment he put a bandage on the arm, and then, as she testified, told her he was going away for ten days or two weeks on his vacation. He was away for five weeks, and when he then examined the arm he found that the bones had slipped from their positions, overlapped, and formed a union, and thereby caused a deformity, which would apparently be permanent unless the arm should be refractured and the bones allowed to unite in proper position. The physician's side of the story was that he told the woman he would be away for two or three weeks, and if she wanted him to call again she must send for him. The point at issue in fixing the liability of the physician was, which was the correct account of his going away. That issue was left to the jury, which brought in a verdict of $2,000 for the woman. This verdict was considered excessive by the trial judge, and the woman consented to have it reduced to $500. In affirming this judgment the Appellate Court said as to the liability of a physician: "A physician who undertakes the treatment of a patient is bound to exercise not only the skill required, but also care and attention in attending his patient until he notifies the patient that his professional relations are terminated. A physician and surgeon engages to bring to the treatment of his patient care, skill, and knowledge; and while, when exercising these, he is not responsible for mere errors in judgment, he is chargeable with knowledge of the probable consequences of an injury, or of neglect in its treatment, or unskilful treatment."

Seaside Hospital Open.—The Seaside Hospital of St. John's Guild at New Dorp, Staten Island, was opened June 15th. The "Lewis Memorial Cottage" erected last fall was also formally opened. This building is a cottage hospital designed for the treatment of very sick infants, and is a model structure for this purpose. It is 103 feet in length by 30 feet 10 inches in width, and contains two wards, each equipped for the care of eight patients. The wards are so arranged that there is an air space of 1,000 cubic feet for each patient, and the ventilating system is as nearly perfect as it can be made.

Proposal to Establish New Consumptive Hospital in New York.—An appeal was made last week by representatives of various taxpayers' organizations in Manhattan and The Bronx to have the city establish outside of the city limits a public hospital for the care of consumptive poor. The Henry law, passed by the last Legislature, gives authority to the city to establish such an institution, and Mayor Van Wyck and Comptroller Coler are now investigating the subject. The agitation was started by the Park District Protective League and the Kingsbridge Improvement Association. Complaints were made to the Health Department and to Mayor Van Wyck that the inmates of Seton Hospital at Spuyten Duyvil were wandering around Riverdale and Kingsbridge and were congregating at the railroad stations and acting in a manner calculated to endanger the health of the community. It was complained that there was lax supervision over the patients, and that they were allowed to wander abroad day and night. The complaints were referred to Comptroller Coler.

PHILADELPHIA.

University of Pennsylvania Commencement.—A new feature of commencement week was a series of clinics and demonstrations arranged to show the alumni the advanced methods of teaching and the complete equipment for purposes of instruction in practical medicine and surgery. Dr. James Tyson was elected President of the Alumni Society.

Dr. Barnes Exonerated.—Dr. C. A. Barnes has been exonerated by the Coroner of the charges preferred against him because of the death of a colored woman who died shortly after being given chloroform during labor. The charge was mainly due to a meddlesome nurse and midwife. The jury found that death was due to exhaustion.

Scarlet Fever at Darby.—An epidemic of scarlet fever is in progress at Darby. Forty cases have been reported, many of them being adults.

State Homeopathic Insane Asylum.—The bill appropriating $250,000 for the construction of an institution to be managed exclusively by homeopaths has been reported favorably in the Legislature. Debate as to the method of control has delayed its passage, which now seems assured.

Milk Inspection by Pediatric Society.—In furtherance of their efforts to establish a pure milk supply for the city, the Pediatric Society has appointed a commission to inspect milk and dairy surroundings and issue guarantees as to the standard of the milk. The commission includes Drs. M. P. Ravenel, Bacteriologist; C. J. Marshall, Veterinary Inspector; and Henry Leffman, Chemist.

State Board Question Again Prominent.—Before the excitement regarding the fraud and investigation relative to the examination held by the State Medical Council in 1899 has fairly subsided, what is apparently a repetition of the fraud has come to light. What were claimed to be the questions for the midsummer examinations to be held this week have been on sale for some days and exorbitant prices have been paid therefor by some candidates for licenses. The day preceding the examinations a local paper published the questions on sale with the statement by Dr. Henry Beates, President of the Examining Board that they were fraudulent. Purchasers of the questions are correspondingly glum and expect a very searching examination as a result of the affair.

A New Suggestion for the Treatment of Focal and Jacksonian Epilepsy.—The article of Dr. J. William White in the *Philadelphia Medical Journal* and *University of Pennsylvania Medical Bulletin* of recent date is the subject of much discussion in local medical circles. Dr. White has not been able to prove a great deal by the two cases in which the method has been tried, but the possibilities are well worthy of study. The method is the result of an effort to combine the effect of operative procedure with sedation of the affected center. A small trephine opening is made over the affected area and 30 minims of a 2-per-cent. eucaine solution injected into the brain tissue. These injections are repeated at intervals. One case was benefited by this procedure, bromides being given after each injection. The other case was also benefited for a time, but the most severe seizure ever experienced followed the last injection before the patient was lost sight of. The method is offered conservatively for trial by the profession.

The Medical Class of 1876.—The 1876 Class of the Department of Medicine of the University of Pennsylvania held its first annual banquet at the University Club, Philadelphia, on Alumni Day, June 11th, and effected a permanent organization for the benefit of its Alma Mater. The following officers were elected: President, Charles A. Oliver, A.M., M.D., Vice-President, William H. Klapp, A.M., M.D., Secretary, Francis M. Perkins, A.M., M.D., Treasurer, Benjamin F. Baer, M.D., with an Executive Committee of twelve members who will meet at the call of the President.

CHICAGO.

New Code for County Hospital.—A new code of rules for the County Hospital is to be drawn up by a special committee of the County Board in conformity with the recommendations of the investigating committee. The line between the functions of the Warden and the medical executives will be sharply drawn.

Gift to Provident Hospital.—In the will of the late Dr. W. S. Caldwell it is arranged that Provident Hospital, of Chicago, shall receive $50,000. St. Francis' Hospital, and the Orphans' Home of this city receive $10,000 each, and the Public Library, $2,500.

Chicago Academy of Medicine.—The annual meeting of the Academy was held a few days ago. Drs. William L. Baum, James G. Kiernan, and Harold N. Moyer were chosen Directors for the coming year.

Annual Meeting of the Physicians' Club of Chicago.—At the annual meeting of this Club, held recently, Drs. W. S. Christopher, Joseph Zeisler and G. Frank Lydston were elected directors, and Dr. L. Harrison Mettler was re-elected secretary and treasurer.

Election of Dr. Stowell.—Dr. James H. Stowell was recently elected president of the American Association of Life Insurance Examining Surgeons.

Appointment of Dr. Baker.—Dr. Miles D. Baker has been appointed first assistant at the Illinois Southern Hospital for the Insane at Anna, and Dr. David R. Sanders, Jonesboro, superintendent of the Annex.

GENERAL.

Free Vaccination for Indianians.—Free vaccination, with pure virus, for the entire population of Indiana, is a proposition before the State Board of Health. It is said the Governor regards the suggestion with favor. Secretary Hurty of the State Board predicts that smallpox will spread to every corner of Indiana until it runs itself out, as has been the case in some foreign countries. The problem has become so large that the general free vaccination scheme is being considered to check the contagion. Indiana ranks with North Carolina ninth in point of order with reference to the prevalance of smallpox. From December 28, 1900, to June 7, 1901, 834 cases were reported with 5 deaths. For the corresponding period last year only 182 cases were recorded.

New Navy Medical Appointment.—Dr. Herbert M. Holfree of Buffalo, N. Y., has qualified for appointment to the medical corps of the navy and will be commissioned an assistant surgeon. Dr. Tolfree was a naval cadet, and

like a number of others, who left the Academy before graduation, he took up the study of medicine to reënter the service as a surgeon.

Col. Forwood to Act as Surgeon-General.—Col. William H. Forwood of the Medical Department, who has been in charge of the important medical depot station at San Francisco for many months past, has been called to Washington to take charge of the Medical Department of the Army during the absence of Surgeon-General Sternberg in the Philippines.

Addition to Providence Hospital.—Coincident with the gratuating exercises of nurses of the class of 1901 at Providence Hospital, Washington, D. C., last week, ground was broken for the new addition to the institution and Nurses' Home, which are to cost $300,000. A distinguished gathering of Government and District officials and prelates of the Catholic Church witnessed the exercises. Addresses were made by Inspector-General Breckenridge of the Army, Surgeon-General Sternberg, and Commissioner Ross.

Another Victim of Appendicitis.—Dr. William Cooper Eidenmuller of San Francisco says he has discovered that dogs have appendicitis. He found it out while performing an autopsy on the remains of a favorite pet. The animal had been ill for a year, and in reviewing his symptoms it is plain that they were identical with those of human beings who suffer from recurrent attacks of this disease.

War on Mosquitoes in Baltimore.—Health Commissioner Bosley has issued an appeal to the people asking their cooperation in the extermination of the mosquito. He advises every householder to pour one gill of kerosene oil into all wells, and a proportionate quantity into all pools and drains where stagnant water may collect, at least once every two weeks.

Suicide Epidemic in Emporia, Kan.—During the past two years in this town of 9,000 inhabitants over thirty persons have committed suicide. To check the epidemic Mayor Morse has issued a second proclamation forbidding the local newspapers from publishing the details. Mayor Morse believes the suppression of this class of news will check the epidemic.

Plague in Bombay and Cape Town.—Plague continues in the city of Bombay, India. Over eleven thousand cases have been reported from December 28, 1900, to April 20, 1901, with 8,721 deaths. At Cape Town, South Africa, the disease is also still present. From February 16, 1900, to May 4, 1901, 572 cases of plague are recorded. Of these 250 died.

National Health League's Plan.—The National Health League, which is heterogeneous in composition, recently held a meeting in New York to further the "grand cause." This, in the language of the League's prospectus, is the promotion of the public health. The League has already announced how this is to be done. All surgery and medication, vaccination and vivisection are to be abolished and a return made to naturalism. Massage, Swedish movement and thought suggestion, diet, reform, grace culture and internal baths are to replace drugs. A stock company capitalized at one million dollars is proposed to promote the teaching of the League's methods and incidentally to manufacture hygienic appliances. Forty-per-cent. dividends are promised to purchasers of the stock.

Treatment of Lupus in London.—The large subscriptions flowing into the London Hospital to carry on the experiment in the use of electric light to cure lupus have caused a little controversy between the surgeons in charge of that work and those using the Roentgen-ray for the purpose at the London Skin Hospital. It seems that the latter experiments have been going on for some time and cost less, because the apparatus used to concentrate the Finsen rays of electric light in the other system is expensive and a long time is required at each exposure. But the use of the Roentgen-ray is always attended with some danger to the patient, and the results at the London Hospital, where experiments have been going on under the direct patronage of Queen Alexandra, are, on the whole, much more satisfactory.

Tuberculosis Congress in London.—Not only has medical science taken the ground that tuberculosis is the most dangerous of all pandemic diseases, but the laity as well have learned to recognize the need of concerted measures to make a determined fight against the ravages of the disease. This is shown very plainly in the list of contributors to the expenses of the Tuberculosis Congress which will be held in London from July 23 to 26. A fund of more than $15,000 has been subscribed to defray the cost of making the Congress a success. Among the leading contributors are found the corporations of the leading cities of the United Kingdom, Parke, Davis & Co., the Dukes of Bedford and Portland, the Marquis of Northampton, the Earls of Derby, Rosebery and Egerton of Tatton with many others of the nobility and gentry. In view of the fact that a large number of physicians from all parts of the United States have signified their intention of attending the Congress an excursion has been arranged by Henry Gaze & Son of 113 Broadway, New York.

Obituary.—Dr. R. J. Martin of Augusta, Me., one of the best-known among the younger medical men of the State, was drowned in Long Pond June 17th. Dr. Martin was graduated from the University of New York in 1887, had been six years a member of the State Medical Board, and was surgeon for the Maine Artillery during the Spanish War.

Dr. William J. Campbell, house physician at the City Hospital of Worcester, Mass., died of smallpox June 15th, after an illness of two

weeks. He contracted the disease while attending a patient in the Hospital. Dr. Campbell was twenty-seven years old. He was a son of Dr. James Campbell, who was at one time city physician in Marlboro. He was a graduate of the Marlboro High School, Boston College, class of '96, and the Harvard Medical School, class of '99. He spent a year at the Cambridge Hospital.

Maurice B. Perkins, Professor of Chemistry of Union College and Albany Medical College, died suddenly June 18th. He had been a member of the Union College faculty since 1865. Professor Perkins was a well-known expert witness in poisoning cases. Maurice B. Perkins was born in New London in 1836, and studied chemistry at Göttengen, Heidelburg, and Tübingen. In 1862 he was appointed assistant professor of chemistry in the College of Physicians and Surgeons of New York City and was afterward assistant in the Lawrence Scientific School at Harvard. He received the degrees of A.M. from the last-named university, and of M.D. from the Albany Medical College. He was the author of a manual of quantitative analysis.

CORRESPONDENCE.

THE ARMY CANTEEN.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I am no little astounded at the action of the American Medical Association in recommending the reinstatement of the army saloon, commonly called the *canteen*. Now, if there was a doubt that the canteen has not been an unmitigated curse to the army, there might have been some reason in the action of the Association. The facts, however, of its demoralizing influence have been so apparent that it is past comprehension why this action was taken.

I wonder if the promoters of reinstatement were conversant with the doings of the fifty canteens that flourished at Camp Thomas, Chickamauga? How about Manila? If this were not a medical journal facts could be piled up in regard to the demoralizing influence of the canteen that would bring the blush of shame to the cheeks of any one who had the good of the country at heart.

It is passing strange that this great Association should pit itself against the Christian sentiment of the country which compelled Congress at two different times to enact laws prohibiting the canteen. I but voice the sentiment of hundreds and perhaps thousands of physicians who feel profoundly hurt by this action of the Association, when we say to these gentlemen, "Beware."

Is not the field of medical science large enough to work in without doing that which would shock and alienate the Christian sentiment of the country?

D. I. MCMILLAN, M.D.

Sunbeam, Illinois, June 14, 1901.

CONGRESS ON TUBERCULOSIS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I should like, through your journal, to call the attention of members of the profession to the important Congress on Tuberculosis which will be held in London from July 23rd to 26th. It is much to be desired that a large contingent from the United States should participate in the work. Many prominent physicians have signified their intention of joining the Congress. Members of the profession wishing to do so should send their names, enclosing five dollars, to Dr. St. Clair Thomson, 20 Hanover Square, London, W., England.

W. OSLER.

Baltimore, June 18, 1901.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, June 8, 1901.

A MEDICAL DEBATE IN THE HOUSE OF COMMONS—THE BIRMINGHAM CONSULTATIVE MEDICAL AND SURGICAL INSTITUTION—MR. CHAMBERLAIN AND THE TRADES-UNION RULES OF THE MEDICAL PROFESSION—AN ATTACK THAT FAILED—ANOTHER SLAP IN THE FACE FOR THE GENERAL MEDICAL COUNCIL—RETIREMENT OF THE DIRECTOR-GENERAL OF THE ARMY MEDICAL SERVICE—THE SECRETARY OF STATE FOR WAR AND THE MEDICAL DEPARTMENT.

THE echoes of a medical controversy made themselves heard last week in the House of Commons with a result that can hardly be considered satisfactory to the medical profession. Some time ago certain prominent citizens of Birmingham conceived the idea of founding what they called a "Consultative Medical and Surgical Institution" where persons unable to afford the ordinary consultant's fee should get expert advice at a reduction of fifty to seventy-five per cent. To enable them to carry out this scheme of cheap philanthropy they hired a young physician who in return for a fixed salary was to give the benefit of what Iago would have called his "gained knowledge" to such as might seek counsels of him. The physician in question, Dr. Ward Irvine, is a graduate both in Arts and Medicine of the University of Dublin, and a man of respectable attainments; his age, however, precludes the possibility of his having had much experience, and unless it be assumed that he is a heaven-born genius who has, like Gil Blas, mastered the whole art at once, he cannot yet have acquired the fulness and ripeness of knowledge that are looked for in a consultant. This is a simple matter of fact which cannot justly be imputed to him for unrighteousness. But he was unfortunate in his friends, or as they might more correctly be styled, his exploiters. These gentlemen, foremost among whom is Mr. Arthur Chamberlain, a brother of the Right Honorable Joseph, are not of the kind who do good by

stealth and blush to find it fame—unless the text be interpreted in a sense not intended by the poet as meaning that they do good by stealing from the legitimate profits of the medical profession and blush when they are found out. They billed the city of Birmingham with advertisements of their institution in which the professional titles and attainments of Dr. Ward Irvine and the advantages of consulting him rather than the general practitioners were set forth with a crudity of style which would have been unseemly in the case of a hairdresser. These advertisements brought Dr. Ward Irvine last November under the ban of the General Medical Council which is the chief disciplinary authority in the medical profession of this country. He was adjudged guilty of "conduct infamous in a professional respect," and his name would have been struck off the *Medical Register*, a penalty which virtually means expulsion from the profession, had not the Council, in view of the offender's youth tempered justice with mercy. He was accordingly allowed six months to reconsider his position, and a few weeks ago as the time of grace was nearing its end, he severed his connection with the Consultative Institution. This was naturally hailed as a victory by the consultants of Birmingham whose zeal for a high standard of professional conduct had been perhaps too obviously stimulated by the fear of being undersold. On the other hand the promoters of the Consultative Institute are unwilling to accept defeat, and the Birmingham newspapers are full of the clamor of the contending parties. The quarrel, however, though amusing enough, was of merely local interest, till suddenly the matter came before the British world by being made the pretext for an attack on the Secretary of State for the Colonies in the House of Commons.

It happened in this wise. It was announced the other day that Dr. Ward Irvine, who be it remembered, is still under the censure of the General Medical Council, had been appointed one of His Majesty's Inspectors of Schools. This, it may be explained, is a position of some importance which has been held by not a few men of mark, among them being Matthew Arnold, the prophet of "culture." It was tolerably clear that a job had been perpetrated. Mr. Arthur Chamberlain had recently to admit in a court of law that the name of his big brother had been used, though without his knowledge, for the pushing of the wares of a commercial firm of which he is a member; and it seemed at least a probable conjecture that the same omnipotent influence had somehow been utilized for the purpose of administering a snub to the General Medical Council. For that is the key to the right understanding of the situation. The appointment of Dr. Ward Irvine was made by the Council of Education, a government department which, like the General Medical Council, is under the authority of the Privy Council. That the one Council should, by implication, bless a man whom the other had banned, and that it should do so in a high-handed fashion without any reference to the sister authority, can only be interrupted as a deliberate slight. The matter is all the more significant because this is the second time within two or three months that the General Medical Council has been ignored by the Government.

As was told in a previous letter, the clause of the Medical Act reserving to the Crown the right to accord recognition to foreign degrees under certain conditions was made applicable to Italy in direct opposition to the recommendation of the General Medical Council; and now we have its disciplinary authority, which is the chief purpose of its being, disregarded with even greater official insolence. A strong protest may be expected from the Council, which will hold one of its half-yearly sessions in this month of June.

As has already been hinted, the case was mismanaged in the House of Commons. One of the medical Members, Sir Walter Foster, of whom mention was made in a previous letter, is a bitter political enemy of Mr. Joseph Chamberlain, and he seems to have thought that he saw in the affair an opportunity of a flank attack. He put up another Member to open the attack, but that skirmisher was speedily driven back, and Foster had to come to the rescue. He is usually a pretty skilful tactician, but on this occasion he cut rather a sorry figure. Had he come forward frankly as the champion of the General Medical Council, he might have made a good fight; but he has a spite against the Council, in which he failed to secure a seat three or four years ago, and his advocacy was half-hearted and ineffective. He kept repeating that Dr. Ward Irvine had been adjudged guilty of "infamous" conduct, whereat the House howled, and that he had not cleared his "character," whereat it laughed. The attack on Mr. Chamberlain was a fiasco, and the net result of the debate was to place the medical profession in a somewhat odious light before the public. It was made to look as if it were bent on hounding to ruin a man guilty of nothing worse than placing a lower price on his labor than the standard fixed by what Mr. Chamberlain bluntly termed "the trades-union rule of the medical profession." The fact is that the words "infamous in a professional respect" which are used to designate unprofessional conduct, though found in the Statute, are in practice prejudicial to the profession, as they are liable to such misunderstanding as Mr. Chamberlain was guilty of.

A curious proof of the contemptuous indifference with which our statesmen regard medical matters was afforded by the statement of Sir John Gorst, Vice-President of the Privy Council, that neither he nor the President, the Duke of Devonshire, had time to read the minutes of the General Medical Council, and were therefore unaware of the charge against Dr. Ward Irvine. As these two members of the government are generally believed to enjoy a superabundance of leisure, this statement can only be taken to mean that they do not consider the proceedings of the

General Medical Council worthy of their attention.

The Secretary of State for War has apparently succeeded in his object of driving the Director-General of the Medical Service of the Army out of his office. On May 31st, Surgeon-General Jameson retired two years before his time. It is said that Mr. Broderick made a mistake as to the Warrant (there have been some half dozen of them in the last twenty years) under which Jameson held his appointment, and the latter compromised the matter by consenting to retire immediately on the full pension he would have been entitled to had he served out his time. It is thought likely that he will receive a further solatium in the form of a K. C. B. which carries with it the title of "Sir" and makes the wife's plain "Mrs." into "My Lady."

Surgeon-General Jameson will probably be succeeded by Surgeon-General William Taylor, now principal medical officer of the forces in India and one of the ablest officers in the service. But such scant official courtesy does the Secretary of State for War think it necessary to extend to the medical service that the staff at the headquarters of the department are still in complete ignorance of the arrangements made by Mr. Broderick for carrying on the business of the office during the interregnum.

TRANSACTIONS OF FOREIGN SOCIETIES.

Freneh.

RACHICOCAINIZATION—INTESTINAL OBSTRUCTION —SYPHILITIC PUPILS.

BAZY, at the Société de Chirurgie, May 15, 1901, reported an experience with special cocainization for the removal of a tumor from an irritable bladder. After the injection had been given the patient suffered from pallor, fear, severe vomiting and headache, and the bladder had lost not the slightest degree of its irritability. The lesson to be suggested appears that cocaine administered in this way is not applicable to operations of which lithotrity is an example. Dilatation of the anus is probably another procedure which would not be fully successful with cocaine in the spinal canal. In short, cocaine should not be administered until the reaction of the patient under it has been fully demonstrated by other means of administration. In general it is better to employ an anesthetic which is under the control of the administrator. Cocaine after its injection passes at once beyond the power of the administrator to cease its more active effects.

GÉRARD-MARCHANT said that he had himself had only one experience with spinal anesthesia, but felt that it was worthy of note. The woman had a large uterine myoma and a mitral regurgitant murmur. The injection was made by Tuffier of three centigrams of the drug. In twenty-five minutes after the method of Doyen, he removed the uterus. The anesthesia was entirely complete and there were no unfavorable circumstances or sequelæ attendant upon the operation.

ROUTIER said he had tried spinal cocanization five times with satisfactory anesthetization except once when a colpoperineorrhaphy was painful to a slight degree while the sutures were being inserted. He has abandoned the method chiefly because of the inherent in the consciousness of the patient. He does not care to operate with the patient one of the spectators.

GUINARD said that a woman under his care had a spinal meningitis secondary to a large abscess in the neck. Owing to the persistence and degree of the symptoms he determined under cocaine to explore the spinal canal. He injected the drug into the subarachnoid space, but found not the slightest possible decrease in the pain.

BROCA, in behalf of Froelich (Nancy), reported a case of intestinal occlusion due to the torsion of the small intestine about its own mesentery. He contented himself with performing a simple artificial anus. At the autopsy, not only was the complete twist in the mesentery found, but also a tight stricture in the colon due to the band formed by the twisted mesentery. It is evident that had the abdomen been widely opened and an evisceration done, the outcome might have been different.

QUÉNU stated that he had operated on a woman for an extensive pelvic peritonitis due to an old appendicitis. The patient did well for the first week and then developed signs of intestinal occlusion. An artificial anus was made which, however, gave only temporary relief. A laparotomy on the eighteenth day showed a mesenteric torsion. The patient died two days later.

SCHWARZ said he had seen one woman who for forty-eight hours had given signs of intestinal obstruction of a severe grade. The depression of the patient was so extreme that he tried electricity. At the autopsy an extensive torsion of the mesentery was found.

BABINSKI, at the Société Médicale des Hopitaux, May 17, 1901, stated that in collaboration with Charpentier he has shown that the abolition of the reflexes of the pupils, especially that for light when permanent and independent of any globular disease and paralysis of the third pair of nerves is an almost infallible sign of syphilis, both hereditary and acquired. He exhibited four patients in whom the condition was very well developed. Three had confessed to acquired syphilis and the fourth in every probability was the victim of it by heredity. In all four there was a lymphocytosis of the cerebrospinal fluid. He concluded that abolition of the pupillary reflexes without other manifestations of disease of the nervous system is a sign that syphilis exists in that system and makes the patient a candidate for tabes dorsalis, diffuse cerebrospinal meningitis or cerebrospinal syphilis.

Appointment of Dr. Coughlin.—Gouvenier Hospital has added the name of Dr. John H. Coughlin of East Broadway, New York, to its staff of visiting physicians.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

The Twenty-Sixth Annual Meeting, Held in Chicago, May 30, 31, and June 1, 1901.

An Address of Welcome was delivered by Dr. Fernand Henrotin of Chicago which was responded to by the President.

Intraligamentous Cysts; Their Diagnosis and Treatment.—This paper by Dr. Chauncey D. Palmer of Cincinnati had special reference to the diagnosis and treatment of these tumors. What is needed is a classification that is helpful in the way of diagnosis and treatment. He spoke of oophoritic, paroophoritic and parovarian cysts. The oophoritic cysts are the hydrops folliculorum, and the unilocular and multilocular cysts. The oophoritic have a Graafian follicular origin and are rarely papillomatous. The paroophoritic cysts start from the hilum of the ovary and are papillomatous. All kinds of cysts, whether oophoritic, paroophoritic or parovarian, may grow into the folds of the broad ligament and become intraligamentous. The paroophoritic cyst is most apt to take on this special course of movement in its progressive development. All ovarian cysts of whatever kind should be removed by surgical procedures, and the sooner the better. But the removal of intraligamentous cysts demands the most correct knowledge of the parts and surroundings and superior skill. The essayist then dwelt upon the advisability, if not necessity, of operators availing themselves of the extraordinary opportunities, when the abdomen is opened, to see and to feel and to map out the morbid conditions, and determine what methods are best to adopt in the removal of pelvic growths. Intraligamentous cysts are, as a rule, easily peeled out of the broad ligaments. Enucleation, first suggested by Dr. Mynter of Buffalo can be done, but it ought only to be attempted when the attachments are superficial. An attempt begun in the old way on some intraligamentous cysts may have to be abandoned as an incomplete operation, or as inoperable. Many such patients have died on the table. He referred to the danger of wounding the ureters, or uterine arteries, and then he earnestly advocated the advisability of completely exsecting the uterus as well as the appendages thereof, when the cysts are bilateral, and where they are deeply embedded within the surrounding tissues. This new method of procedure, while seemingly the more radical way, is the only rational method of a skilful surgical extirpation of the diseased structures. He lauded highly irrigation of the peritoneal cavity with gallons of hot salt water after section, and the measures he had utilized of a continuous peritoneal irrigation of hot sterilized water, used for hours or days, in many cases of post-operative septic peritonitis.

Improved Technic in the Surgical Treatment of Uterine Myomata.—Dr. Wm. H. Wathen of Louisville, Ky., contended in this paper that the perfection of technic in operations for the removal of uterine or pelvic myomata is the result of the application of the variety of details suggested and practised by different surgeons. Operators no longer speak of hysterectomy as an operation peculiar to anyone, nor can they in many instances outline in advance the complete technic to be observed or carried out in an operation. The dangers during the operation are hemorrhage or injury to the bladder, ureters or intestines, and if the surgeon is prepared to avoid these, and operate speedily, there is hardly a condition that may not be successfully treated: Unless there is some contra-indication, myomata not larger than a fetal head may be easily removed *per vaginam*. If the operator uses well-constructed forceps, he will not wound the bladder, the intestines or the ureter, the last-named of which, if necessary, may be protected by ureteral catheterization, also to be used as a means of protecting the ureters in the suprapubic method. Experience will aid in the selection of cases suitable for the vaginal method. While the author has removed with ease uterine myomata twice the size of a fetal head, he has had great difficulty in removing one much smaller. The conditions most favorable for the vaginal method are a large pelvis, a large and easily dilated vagina, and a soft variety of tumor that can be easily morcellated. The operation is best performed by the almost total exclusion of retractors other than the fingers; well-constructed forceps are important, and, with few exceptions, no ligatures should be applied until the tumors are removed. There are many cases of uterine myomata where an operation is indicated, in which the tumor or tumors may be enucleated, leaving the uterus capable of performing its normal functions; where this can be accomplished myomectomy should be the method of election.

Painful Menstruation as a Factor in Determining Character of Operations on the Uterine Appendages.—A paper on this subject was read by Dr. Philander A. Harris of Paterson, N. J. The author divided dysmenorrhea into primitive and acquired or secondary. The primitive form included all cases in which dysmenorrhea dated from the commencement of the menstrual function. Acquired or secondary dysmenorrhea is that form not present at the onset of menstruation, but arises during menstrual life, menstruation having been previously painless. Extra-uterine suppurations so commonly resulting from gonorrheal infection of the uterus, and from the ordinary infections of childbirth and abortion, are of such frequent occurrence as to quite over-

shadow in importance all other causes of acquired dysmenorrhea. Not all cases of suppuration in the uterus or tubes cause painful menstruation. A small percentage of such cases, even in the presence of extensive and long-continued suppuration, menstruate painlessly. Tubal suppurations may, and usually do, cause painful menstruation before the development of ovarian abscess. This is proven by the fact that surgeons so often have exsected both suppurated tubes, at the same time leaving both ovaries which appeared healthy, with the arrest of all pelvic pains and restoration to health, including a cure of the dysmenorrhea. Ovarian abscess frequently develops from tubal suppuration, with the effect of increasing, modifying or localizing not only intermenstrual pains, but also the pains of menstruation. Pronounced and persistent primary dysmenorrhea, or the dysmenorrhea which existed from puberty, will probably not be obliterated by the simple excision of diseased tubes. By excision of a tube is meant its removal to the uterine mucosa by making an elliptical incision in the uterus about the tube and closing the chasm with sutures. The author's partially conservative surgical work in this connection has shown him that, while he has maintained for about ninety-five per cent. of all women thus operated on the item of menstruation, he has had a higher percentage of relief and symptomatic cures and far greater satisfaction with the results obtained than accrued from his former and more extensively mutilating and exsective operations.

Status of Menstruation.—Dr. E. C. Gehrung of St. Louis, Mo., read a paper with this title. Menstruation is not, as has been supposed, a special function of the generative organs of woman, but only the perverted counterpart of the estuation of the lower animals. This transformation into a monthly "hemorrhage" (menorrhagia) has generally been brought about by the necessities and results of the social, moral and connubial life of mankind, as well as through the transmission by inheritance of certain debilities of the generative apparatus, and more especially by the erect position and its natural consequences, assumed by the human species. This fact being admitted, the profuseness and prolongation of the sanguineous loss are proof that it is now a physiologico-pathologic condition, predisposing to anemia and all its direful consequences, preëminently to the nervous system. In the great majority of cases the quantity of blood lost during so-called normal menstruation is an unnecessary and therefore pathologic waste of the very essence of life. It stands to reason that in all cases of depressed vitality this loss should be reduced as much as possible and by all means of disposition. The best means for controlling the waste is the vaginal (not uterine) tampon, applied secundum artem. Whenever curettage is not indicated or applicable, and where it has failed in gaining the desired result, the tampon is the means indicated. Chronic and acute inflammation of the pelvic organs are contra-indications.

The Age of First Menstruation in the United States.—Dr. G. J. Engelmann of Boston, Mass., read a paper on this subject. Over 10,000 observations as to the time of first menstruation of American-born women, many with reference to points never before investigated, here or elsewhere, gives him ample material for an authoritative solution of the questions involved. These observations, from his own practice and that of helpful friends, are many, and the identity of results obtained in far distant points, Montreal and New Orleans, St. Louis, Cincinnati, and Boston, vouches for their correctness. Furthermore, they are corroborated by all previous records, a total of 6,000, in such points as these may cover. The mean age of first menstruation in this country is 13.9 or 14 years, the same in the United States and Canada. Climatic differences in no wise influence pubertal development within the bounds of the North American continent; the American-born, be they of American (14.1), German (14.3), Irish (14.3), or French (13.6) parentage of the same class, attain puberty at the same age in Montreal, St. Louis or Boston; the negro does not vary (14.05), whether in New Orleans or St. Louis. The greatest variation caused by the extremes of all influences is one year, from 13.5 in the girl of highest refinement and education to 14.5, which is the period for the American-born of the laboring classes of German and Irish parentage; in other countries the difference between the extremes of social classes is from two to three years. The native American is more precocious than the American-born of foreign parents, but the latter closely approximate the American of American parentage, even in the first generation.

Cancer of the Uterine Fundus.—A paper with this title was read by Dr. J. M. Baldy of Philadelphia. Carcinoma in any part of the body is so well known for its virulence that there can be no surprise at the results of this disease recently reported from so many sources, where the uterus has been the organ attacked. It must be admitted that carcinomata of the same variety are intrinsically much the same as far as the disease itself is concerned, but the location of the disease renders the practical aspect of the case widely different; and of all portions of the body in which it is safest for cancer to occur, if the word safe can be used in this connection at all, the fundus uteri is that portion. It is with the object of calling the attention of the profession to, and emphasizing as strongly as possible, the wide practical difference between cancer of the cervix and cancer of the fundus, that this paper is presented. It has been said that practically all patients with cancer of the

cervix eventually die of the disease; while practically all those with cancer of the fundus remain well if operated upon. This statement is more generally true than one would suppose at first glance. It has been my own, and the experience of other surgeons. Less than five per cent. of cases of cancer of the cervix are cured, no matter what line of treatment is followed. Twenty-four cases of cancer of the fundus have passed through my hands, a fairly large experience for one man. Of these, three were either too far advanced for operation, or refused operative treatment. On the remaining twenty-one cases hysterectomy was performed by the vaginal method, the abdominal method or the combined vagino-abdominal method. Two of the twenty-one cases died as a result of the operation. Of the nineteen remaining cases, all are alive and well to-day, with two exceptions. One of these died of pneumonia seven years after operation. It is strongly suspected from the reports that the other one has a recurrence. Making all allowances for mistakes and the general unreliability of statistics, the fact stands out strongly that about seventy-five per cent. of these cases are well and free from signs of cancer, as against five per cent. or less of cancer of the cervix.

The Status of Hysterectomy for Uterine Cancer.—Dr. Cyrus A. Kirkley of Toledo, Ohio, presented a plea for conservatism in the surgical treatment of uterine cancer, and contrasted its pathology and treatment of half a century ago with that of the present. While we have a revised nomenclature as to the varieties of uterine cancer, actual knowledge of the disease has not materially advanced. Due credit was given the advocates of vaginal hysterectomy for their skill, and for whatever pathological fascination made it too general, and proper indications for it were too often disregarded, and as often misunderstood. Instances were given pointing out this truth. With these discordant views as to the propriety of so serious an operation, the primary mortality of which is at least ten per cent., one might well hesitate in its adoption. The operation should be done at the early stage, when microscopic examination is necessary for a correct diagnosis. Most cases have passed the limits of radical operation when they apply to the surgeon.

Prolapse and Procidentia of the Uterus.—In this paper Dr. Henry T. Byford of Chicago holds that the essential feature of prolapse is the want of supporting power of the pelvic connective tissue. To suture the uterus to the abdominal walls is to support the pelvic connective tissue by means of the uterus and is wrong and inefficient. The best and most rational method is to draw up and attach the peri-uterine tissue and thus keep the uterus up by means of its natural supports. In addition to the ordinary operations for lacerations and relaxation at the vaginal outlet, the following method is proposed: (1) Shorten the round ligaments intraperitoneally, making one large loop of each ligament, and then stitch the loop to the parietal peritoneum a little above, and internal to, the internal inguinal ring. (2) Suture the infundibulo-pelvic edges of the broad ligaments forward to the parietal peritoneum, external to the internal inguinal rings, as high as they can be drawn without much resistance. Then suture any available relaxed part of the broad ligament forward over or beside the round ligament loops. (3) Put a suture through the base of each round ligament at its junction with the uterus, and suture it to the peritoneum over and beside the bladder. (4) Examine the sacro-uterine ligaments. If the peritoneum corresponding to their location is not drawn up and made somewhat taut by the new position of the uterus, or if the cervix sags far forward toward the vaginal entrance, take a short fold or tuck in it and suture it to the broad ligament beside the cervix, and perhaps slightly to the edge of the cervix, getting as broad a peritoneal apposition as possible. (5) Search for the remains of the urachus at the lower end of the abdominal incision. Start a slit in the peritoneum an inch above the lower angle, and half an inch on either side, and extend them downward and outward to the bladder wall. Make a transverse incision on either side, uniting the upper end of the slits to the abdominal incision. Separate the peritoneum between these slits, including as much connective tissue as possible, from the underlying fascia, and there will be formed a partly divided flap of connective tissue and peritoneum with the urachus near its center. Fold or twist this loosely into a sort of cord and attach it to the rectus fascia at the edge of the incision, and high enough up to draw the bladder and anterior peritoneal wall well up. This suspends the bladder somewhat after the manner described by Dawson.

Panhysterokolpectomy, a New Prolapsus Operation.—This was the title of a paper read by Dr. George M. Edebohls of New York. This operation consists in complete removal of the uterus and vagina, followed by operative obliteration or columnization of the bed of the genital tract. The tubes and ovaries are not disturbed, if healthy; if diseased, they are removed with the uterus and vagina. Obliteration and columnization of the bed of the removed uterus and vagina is effected by means of from seven to nine buried pursing sutures of chromicized catgut placed about two to two and a half centimeters apart, and running parallel to each other. Each suture gathers the raw surfaces from the periphery in circular fashion, and draws or purses them together in the median line. It is buried by being pushed upward toward the abdomen, while the next suture is being tied beneath it.

Pus in Abdominal Operations.—As a result of his observations during the past seven years, Dr. Hunter Robb of Cleveland has become convinced that operators not infrequently err in carrying out radical abdominal procedures when the patient's resistance is in such a lowered condition that she is very apt to succumb to the shock of the operation *per se*. Such a condition must always be given careful consideration when deciding for or against operative interference during an acute attack of a localized or more or less generalized pelvic peritonitis. Believing that this factor has a very important significance in influencing results, the speaker has made it a rule during the acute stage of a pelvic abscess to defer an operation so long as it seems safe to do so. In the meanwhile, the patient is kept perfectly quiet on her back in bed, and heat in the form of flaxseed poultices or turpentine stupes is applied to the abdomen. In addition, a vaginal douche of a gallon of a warm one-per-cent. solution of carbolic acid, or a saturated boracic-acid solution, is given twice daily. For nourishing the patient he depends upon nutritive injections entirely. Anodynes and heart stimulants are given, if necessary.

Removal of the Female Urinary Bladder for Malignant Disease.—A paper with this title was read by Dr. Matthew D. Mann of Buffalo, N. Y., who said that the operation for removal of the bladder has not received enough attention in this country, there being very few cases on record. Cancer of the bladder is rare, but is the commonest form of growth found in this viscus. The diagnosis can be made by the symptoms, the use of the cystoscope, palpation and the examination of the urine. Treatment may be removal through the urethra, the vaginal septum, or by suprapubic cystotomy. The operations are the removal of the growth and its base, resection of part of the bladder or cystectomy. Indications for total removal are multiple growths, return after removal, extensive involvement of the base, and extension of cancer of the cervix uteri into the bladder. The ureters need no attention at the time of the operation, as by the removal of a portion of the anterior vaginal wall they will discharge into the vagina. If possible, the ureteric openings into the bladder should be left intact. This will rarely be impossible. He does not believe in uretero-intestinal anastomosis. The vagina can be used as a receptacle for the urine, as was done by Pawlik. If this be done, there will be little danger of infection traveling to the kidneys, as the newly-made bladder can be kept clean. Mann reports two cases, both of which recovered from the operation, and has collected from the literature fourteen cases more. He concludes that in certain malignant disease of the bladder, total extirpation is a justifiable operation, offering no serious difficulties to an experienced abdominal surgeon, and giving the patient a chance for a comfortable continued existence.

Total Extirpation of the Urinary Bladder.—This paper was read by Dr. J. Wesley Bovée of Washington, D. C. The following conclusions were based upon a study of ninety-six cases collected from literature: (1) Until a more satisfactory plan of disposal of the ureters is found, cystectomy should never be undertaken for conditions other than exstrophy, when partial extirpation of the organ is possible. Even a very small portion of the bladder into which the ureters may be debouched is practically free from danger of infection incident to bowel grafts, and further such disposition of the ureters is more easily executed. (2) For exstrophy of the bladder the Maydl and the Pozzi operations are quite satisfactory, though the danger of infection seems ever present. (3) Rectal graft of the ureter in its continuity and skin-grafting of this duct are highly dangerous. (4) Uretero-vaginostomy is practically free from ascending infection, though it gives far from perfect results. (5) Urethral graft of the ureter seems free from infection, but the constant dribbling of urine is but slightly ameliorated by the use of the urinal. (6) The Mauclaire-Gersung operation is worthy of further application, inasmuch as it provides for both sphinctered bladder and bowel.

Shock, from a Clinical Standpoint.—Dr. Eugene Boise of Grand Rapids, Mich., read a paper on this subject. The basis of the theory of paresis is the thought that the extremely low arterial tension of shock is inconsistent with vasomotor stimulation, which, by causing arterial contraction, should give high tension. On the contrary, the symptoms of shock can, in reality, only be explained by the theory of extreme *stimulation of the entire sympathetic system*. Laboratory experiments have demonstrated that extreme stimulation of the cervical sympathetic will cause cardiac and arterial *spasm* with consequent *low* arterial tension by reason of incomplete diastolic relaxation of the heart. Postmortem records show that in fatal cases of shock the heart is found contracted and empty, even ruptured, showing a condition of extreme *stimulation* of the vasomotor system, rather than paresis. Nitrite of amyl and nitroglycerin are noted arterial relaxants, and yet they are very beneficial in shock. So, also, with strychnine. The opinion of operators of large experience is that to be of benefit it must be given in large doses. And yet all therapeutists agree that in such doses strychnine paralyzes the vasomotor center and the intracardiac ganglia, and therefore is absolutely contra-indicated if the vasomotor nerves are already paretic. So also with normal saline infusion. To derive the greatest benefit it should be used intravenously and at a temperature of 118° or 120° F.

Resections and Exsections.—In this paper Dr. Fernand Henrotin of Chicago presented

the salient points concerning the questions involved in resection of the ovaries and tubes, as there is still much doubt regarding the results obtained, and as to the proper methods to pursue. He considered the subject of resection and exsection under three heads. (1) Diseases involving the tubes. Salpingotomy and tubal resection is a most undesirable operation, and only the most formally expressed desire for offspring on the part of the patient, after explanation of the uncertainty of results, will warrant their performance. Pyosalpinx always demands exsection, and any tube materially damaged by any disease should be removed in its entirety. (2) Ovarian disease. All diseases of the ovaries, adjudged to be nonmalignant, can be cured, and should be treated by resection of the diseased portions only. Recent ovarian abscess can be cured more quickly, more certainly, and with less danger by vaginal incision when this is practicable. When the abscess is of long standing, the sac should be removed, but even then some healthy ovarian tissue can almost invariably be preserved. (3) Chronic composite diseases. In most diseases of a composite nature in young women, when the tubes and ovaries are materially and equally involved, salpingectomy with ovarian resection is the most satisfactory operation, the uterus being retained.

These three topics were taken up *seriatim* and discussed at great length. The author has performed at least two hundred and fifty operations which might be classified as salpingotomies, salpingectomies, and ovarian resections. He could safely state that 40 per cent. may be termed delayed and partial cures, or failures. Of this, 40 per cent., the heaviest proportion by far comes from such as have had salpingotomy or tubal resection performed. The next most complaining class are those in which the ovaries alone were resected and the least suffering and the best health are found among those in whom the tubes when affected were entirely exsected and the whole or portion of the ovaries was removed. He has not had to reoperate more than five or six times. By salpingotomy the author means opening into the lumen of the tube, and by tubal resection is meant the removal of a portion of a tube including the mucosa, and his statement presumes a material pathological alteration in the portion removed or incised. Under such conditions, he had no hesitation in stating that for every baby born there would be forty uncured or partially cured patients.

The President's Address.—The subject chosen was the future of gynecology as a surgical specialty. The general scope of Dr. Van de Warker's address was given in an anecdote of a noted ovariotomist who was invited by the President to contribute a paper to the Section on Obstetrics and Gynecology of the American Medical Association at the session at which he presided as Chairman. The ovariotomist declined on the ground that he was not a gynecologist; that ovariotomy and hysterectomy and other abdominal operations were general surgical procedures, and were more in the line of the general surgeon than the gynecologist, and wound up his letter of refusal by predicting that the time was not far distant when these operations would be by general consent of the public in the hands of the all-round surgeon. The speaker asks the question if that time has not arrived? The influence of the gynecological surgeon will always be felt. To him as a man of last resort will always be left the question of methods and expediency. Total hysterectomy for cancer is yet on trial. It is already abandoned by able men, while others are hopeful of good results. Will the final verdict upon this question be given by the general or special surgeon? The latter is trained in dialectics, he will bring to bear on the ultimate solution of such a problem qualities which the former cannot possess, because he cannot have universal knowledge and be the possessor of unlimited technic. All the great abdominal operations which are so eagerly exploited by the surgeon at large passed through this ordeal at the hand of the gynecologist, and were turned out finished procedures both in expediency and method into other hands. The day is nearly passed when great gynecological reputations can be made by the exploitation of a few operations. That belonged to the formative period of the art. But there is enough yet left for gynecology to explore and add to the sum of its literature. The subject of pelvic dynamics is still left in research. We know little of the subject of genital ptosis in women; our treatment of uterine displacements is rank empiricism. The physiology of the pelvic organs must at last be given its true value by the gynecologist rather than by the physiologist in his laboratory, as it must be studied functionally rather than structurally. Gynecology will always have its future, possibly brighter, more generally fraught with usefulness from the fact that its best minds are no longer concentrated upon matters purely mechanical, and which appeal to a comparatively few unfortunates, but because it will embrace in a broader scope all humanity. These are a few of the problems which the gynecology of the future must meet and in which men trained as we are, ought to feel a profound interest. We not only study the diseases peculiar to women, but we must also study social conditions that may tend to disease. There is no other department making such imperious demands upon its advocates as the gynecology of the present, and we may be sure that it will not diminish in the future. There is nothing that contributes to the mental equipment of a man that the gynecologist can do without. The ascendancy of gynecology as a surgical department will in no manner diminish, be-

cause it shares its surgical triumphs with all who have the skill and knowledge to follow its lead; on the contrary, it will have a greater moral power when its advocates can find a field, broad and in close touch with humanity all about, beyond the limits of the operating-room. Would not the gynecologists of France be doing a better service to their country and to science if they were to find the cause and conceive the remedy for the decadence of the birth-rate, rather than bend their energies in finding a new way to perform an operation? If surgery has its limits, there are no limits to higher gynecology. Either the word is badly constructed, or its meaning only half understood among those who attempt to limit it to surgical lines.

Indications for Cæsarian Section as Furnished by Pelvic Contractions.—Dr. J. W. Williams of Baltimore, Md., read a paper with this title. In 2,123 cases in the Obstetrical Department of the Johns Hopkins Hospital, 278 (13.1 per cent.), had contracted pelves. The pelves were measured both externally and internally, and designated as contracted when the conjugata vera was 10 cm. or less in generally contracted, and 9.5 cm. or less in flat pelves. Nine hundred and forty-one of the patients were white and 1,182 black. Contracted pelves occurred in 6.91 per cent. of the former, and 18.1 per cent. of the latter. That is, in every fourteenth white and every sixth black woman. One hundred and ninety-nine of the 278 cases ended spontaneously (71.58 per cent.) The number of spontaneous labors decreased with the increase in the pelvic contraction. In view of the markedly-improved results following Cæsarian section, the indications for its performance should be widened. Thus we find that Zweifel, Olshausen, Reynolds, Bar, Charles and Cragin have performed 162 operations with 5 deaths, a mortality of 3 per cent. He therefore believes that in uninfected cases the upper limit for the absolute indication for Cæsarian section should be advanced from 5.5 to 7 cm., and the relative indication from 7 or 7.5 to 8.5 for flat, and 9 cm. for generally contracted pelves. With the absolute indication the operation should be done either at the end of pregnancy or the onset of labor; but when the relative indication is present the woman should be allowed to go into the second stage of labor, and have bearing-down pains for one hour, when, if the head does not show signs of molding or descending, Cæsarian section should be performed, instead of forceps upon the movable head or version. So that at present Cæsarian section for the relative indication should compete with high forceps or version, instead of with craniotomy upon the living child, as in the past. On the other hand, if the patient be infected, or her surroundings such that an aseptic operation cannot be performed, high forceps or version should be attempted, followed by craniotomy in case one fails to deliver the child by their means, and Cæsarian section reserved for those cases in which an absolute indication is present on the part of the pelvis.

Circumstances Which Render the Elective Section Justifiable in the Interests of the Child Alone.—This paper was read by Dr. Edward Reynolds of Boston in which form his experience and study of the subject he concludes that no man is justified in performing Cæsarian section as a last resource late in labor, or upon infected or otherwise constitutionally ill women, for the sake of the child alone; but that he who attains to the fullest possible knowledge of his cases beforehand may do the section at the beginning of labor on healthy women, with even less risk to both mother and child than is involved in the performance of unusually difficult high-forceps operations through contracted pelves.

The Technic of Cæsarian Section.—Dr. Matthew D. Mann of Buffalo, N. Y., first discussed the relative merits of the Sänger and Porro operations. He concludes that there is no rivalry, but that each has its proper place. The classical operation should be done in all elective cases, when the woman is in good health, the operation done in time, and all the conditions favorable. The Porro operation should be done when the uterus is septic; when gonorrheal infection is known to exist; when the uterus refuses to contract; when there are large fibroids or ovarian tumors, which cannot be removed without injuring the uterus. Small fibroids usually disappear after pregnancy. Other indications for the Porro operation are disease of both ovaries, when the uterus is torn or ruptured in labor, in cancer of the cervix, when the patient is greatly reduced and bearing the operation badly, in osteomalacia and bad atresia of the vagina. Six operations have been done in Buffalo by four operators, with the loss of one child. One mother died six weeks later of carbolic acid poisoning.

Place of Symphyseotomy as Contrasted with Section.—Dr. Charles Jewett of New York presented the following conclusions upon this subject: (1) Symphyseotomy is still a useful operation within a very limited range of pelvic contraction. (2) It is suited to conditions in which only very little additional pelvic space is required for delivery. (3) It is a valuable recourse, therefore, in cases in which forceps unexpectedly proves inadequate. (4) Axis-traction forceps, with the aid of posture, should always be tried before resort to symphyseotomy. (5) Its results would be much improved by restricting it to pelves with a conjugate of not less than 7.5 cm., three inches. (6) Under equally favorable conditions its total mortality should be no greater than that of Cæsarian section. (7) When the pelvic space permits, it should replace Cæsarian section in the presence of exhaustion. (8) It may be elected primarily as an alternative of Cæsar-

ian section, when the operator can be assured that the degree of obstruction is well within its safe limit. Here the choice of operation is largely a matter of individual preference. (9) Within its proper field symphyseotomy is better than Cæsarian section for an operator of little experience in abdominal surgery.

Relative Merits of Bipolar Version with Slow Extraction and Accouchement Forcé in the Treatment of Placenta Previa.—A paper with this title was read by Dr. Henry D. Fry of Washington, D. C. He said that if we compared theoretically the bipolar method with accouchement forcé we would see that there exists reasons why the former may be considered safer in the hands of the inexperienced operator. In placenta previa a fatal result is usually due to hemorrhage or sepsis. The hemorrhage is unavoidable and incident to dilatation of the os. Consequently the method requiring the least degree of dilatation necessary to perform version will naturally be expected to give the least hemorrhage. After dilatation be obtained in sufficient degree to insert several fingers, further continuance of the process by manual means is likely to endanger the integrity of the soft parts. In other words, the artificial dilatation sufficient to perform bipolar version is comparatively safe, while that necessary for the insertion of the hand and internal version is dangerous. The rapid delivery of the infant in accouchement forcé adds additional risk of rupture. There is one serious objection to bipolar version and slow extraction. The infantile mortality is greater. When interference is necessary before viability or when the fetus is dead, slow delivery is certainly indicated. If the life of the child is endangered during slow extraction, the obstetrician must decide between it and mere rapid delivery with its increased maternal risks.

Scratch-Marks on the Wax-Tipped Bougies in Diagnosis of Ureteral and Renal Calculi.—Dr. Howard A. Kelly of Baltimore exhibited nine drawings made by Dr. Becker, showing scratch-markings made on wax-tipped bougies by calculi in the kidney and ureter; pictures of the calculi and the bougies used were also shown. A mixture of melted dental wax and olive oil, equal parts, was used to tip the renal catheters. This substance produces a smooth and highly polished surface, which on coming in contact with a stone is scratched or gouged in longitudinal striæ. The mucous membrane of the urinary tract cannot possibly affect the waxed surface.

Injuries to the Head of the Newborn.—Dr. Andrew F. Currier of New York contributed a paper which will appear in the MEDICAL NEWS.

Tetanus Following Celiotomy; with Report of Two Cases.—Dr. Henry C. Coe of New York contributed a paper on this subject. In his introductory remarks he stated that tetanus is such a rare complication of abdominal section that many operators of large experience have never had a case. Confident in the power of thorough asepsis to overcome the most virulent germs, we are apt to forget that there still remain some which resist the ordinary methods of sterilization, and against which we seem to be powerless to act, because as yet we do not understand their mode of development, and the nidus most favorable for their growth. Statistics have shown that the disease is especially fatal after ovariotomy and hysterectomy. Tetanus is a rare cause of death after aseptic operations, as shown by reviews of various hospital records. Environment seems to make little difference. In Bellevue Hospital, where conditions are apparently most favorable to development of tetanus, this is almost unheard of, except as the result of wounds received before the patient is admitted. In the General Memorial Hospital, on the contrary, where the conditions are infinitely better, two fatal cases have occurred since the hospital was opened (1887), and both in the service of the writer. In both cases tetanus followed clean operations, after a normal convalescence, and under conditions which were quite inexplicable.

In the first case there was double salpingitis and cystic ovaries were removed. Perfectly simple operation. Convalescence afebrile, though patient was very nervous. Primary union of wound. Out of bed in sixteen days. Complained of slight sore throat and trouble in swallowing. Twenty-first day, up and about. Slight stiffness of neck. Twenty-sixth day, slight spasm of muscles of jaw. Thirty-second day, diagnosis of tetanus made, and 25 c.c. of serum injected under skin. Swallows with some difficulty, but no other symptoms. No rise of temperature and general condition good. Thirty-fourth day, still takes nourishment. Additional injection of serum. During next two days general convulsions. Death on thirty-sixth day. The second case was one of panhysterectomy for fibroid uterus and diseased ovaries and tubes. Absolutely normal convalescence, until ninth day, with primary union, when patient had slight stiffness of the neck. Tenth day, could not swallow. Serum (50 c.c.) injected into vein. General convulsions during night. Second intravenous injection. Death on eleventh day. In neither case were specific germs found in blood or neighborhood of wound. There was increased difficulty of diagnosis, as both patients were hysterical and had no rise of temperature or other symptoms. Treatment was of no avail, though begun too late in first instance. The cases occurred eighteenth months apart, and no others developed in the hospital before or since. No cause was discovered, either in technic, condition of patients before operation (both were in good health and had been long under observation), or climatic conditions. Questions for discussion are (1) Can we pre-

vent the development of the disease, and how? (2) Can we avert the fatal result by prompt resort to the use of antitetanus serum or other treatment? The answer to these questions in the class of cases under consideration is thus far a negative one. It seems to be impossible to discover and act directly upon the focus of infection when it is within the abdomen.

Election of Officers.—The following officers were elected for the ensuing year: President, Dr. S. C. Gordon, Portland, Maine; First Vice-President, Dr. George M. Edebohls, New York; Second Vice-President, Dr. Edward Reynolds, Boston; Secretary, Dr. J. Riddle Goffe, New York; Treasurer, Dr. J. Montgomery Baldy, Philadelphia. Atlantic City, N. J., was selected as the place for holding the next annual meeting.

AMERICAN MEDICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held at St. Paul, Minn., June 4-7, 1901.

Section on Practice of Medicine.

Third Day—June 6th.

(Continued from page 971.)

Amount of Pericardial Effusion.—The amount of fluid contained in the pericardial sac may often be very large. A French surgeon removed the surprising amount of ten liters from the pericardial sac. When the effusion occurs slowly the symptoms are not very acute. Rapid effusion soon causes the heart to labor.

Purulent Pericardial Exudate.—Notwithstanding that the exudate has become purulent, it may be absorbed, leaving scarcely any residue, or it may burrow, finding its way out of the pericardial sac into neighboring structures. The abscess thus formed may point through the precordial region. It may bore through a rib or may by pressure absorption find its way through the sternum. The collection of pus may point in the back, following the course of the vertebræ and simulating very much a Pott's abscess. The abscess may find its way into the lungs, producing a pyopneumonia and pyopneumopericarditis.

Results of Absorption.—When a collection of pus becomes absorbed from the pericardium, there is nearly always considerable residue left. This is prone to calcify like other pus residue and the pericardium may become covered with an inner coating of a hard, bone-like substance. This calcified material may force its way between the layers of the heart, producing serious interference with its function.

Myocarditis.—As the result of a serious pericarditis the heart muscle nearly always becomes affected. Fatty degeneration may set in and active dilatation of the interior of the heart may be the result. More important even than fatty degeneration, which is, however, most familiar to the clinician, is the fibroid interstitial change. As the result of this marked hypertrophy of the heart may occur.

Etiology of Pericarditis.—Dr. Robert B. Preble of Chicago gave, as the result of a series of observations on some 240 cases of pericarditis, his conclusions as to the cause of the disease. Acute primary pericarditis does occur, but is very rare. Pneumonia causes about 34 per cent. of all pericarditis. Rheumatism causes 28 per cent., nephritis 11 per cent. Other well-known causes are sepsis, aneurism and typhoid fever, though they are much less important as etiological factors than the two first named pathological conditions.

Pneumonia as a Cause.—The more extensive the pneumonia, the greater the danger of the pericarditis. The pericardial sac is more apt to be involved with left-sided rather than right-sided pneumonia. Unilobar pneumonia causes pericarditis in one case in forty; bilobar pneumonia in one case out of ten. The mortality of pericarditis complicating pneumonia is very high, amounting to nearly 90 per cent.

Nephritis and Pericarditis.—Pericarditis occurs as a complication of all forms of the nephritis. The coexistence of these two conditions is always ominous for the patient. It is a question whether nephritic pericarditis is due to the presence of toxic, irritating principles in the blood, or to the existence of microbes, which gain a foothold in the tissues because of the lowered resistive vitality due to ineffective elimination.

Primary Pericarditis.—This form of the disease grows rarer as we learn more about the condition. It is probable that there is always some port of entry for the infection though it is often difficult to find it. Where it can not be found the pericarditis is considered as primary. Out of 240 cases of pericarditis, twelve were apparently primary, or idiopathic. After careful autopsy only two were left in this class, and at least one of these was doubtful.

Adherent Pericardium and the Effect It Produces on the Heart and General Circulation.—This paper was read by Dr. Robert H. Babcock of Chicago. It will appear in a subsequent issue of the Medical News.

Pericarditis and Pancarditis.—Dr. Alfred Stengel of Philadelphia read a paper on the relation of pericarditis to endocarditis and myocarditis. He said that pericarditis causes danger in three ways. First, by presenting a focus of infection, second, by the effusion causing mechanical interference with the heart's action, and, third, by being a starting-point for further inflammatory lesions. The mechanical danger from pericardial effusion is not as great as used to be thought. When endocarditis and pericarditis occur together, the heart is usually so crippled that life does not last long. Fortunately this combination is not common. The spread of the inflammatory process to the myocardium is, however, very common. Pancarditis, an inflammation of all three structures, is not as infrequent as might be imagined from its rare men-

tion by clinicians. As a matter of fact the danger in both endocarditis and pericarditis comes more from the involvement of the myocardium than from any other element.

Myocarditis.—Myocarditis has been well recognized by the pathologists for a good while, but has not received its due meed of attention from the clinician. Practically the only form of myocarditis which does receive due attention clinically is fatty degeneration. Cardiac fibrosis is not uncommon with pericarditis. There is always some affection of the muscle, even though this may not produce clinical symptoms. Very slight involvement of the myocardium may produce disturbance of the heart rhythm.

Future of Pancarditis.—Jürgenson says that pancarditis will undoubtedly be the diagnosis of the future in many heart affections now considered to be limited to one part of the heart structure. The prognosis of any form of heart lesion depends on the extent to which the myocardium may be involved.

Tuberculous Pericarditis.—Dr. C. F. McGahan of Aiken, S. C., said that tuberculous pericarditis is much more frequent than has been thought. Many an obscure case of heart trouble in severe anemic conditions, or in tuberculosis of other organs, is really due to a tuberculous pericarditis. Later in the disease there will come a form of cachexia as the result of interference with nutrition through the circulation. When the pericardial sac is aspirated the bacilli may or may not be found. When they are found the diagnosis is clear. Negative examination, however, gives no assurance, because bacilli are often infrequent and inoculation experiments are needed in order to demonstrate their presence. Dr. McGahan reported two cases of tuberculous pericarditis which have come under his observation. In one of them there was tuberculosis of the right apex with cavity formation but the condition had been quiescent and the case was progressing very satisfactorily when suddenly pain and dyspnea developed. The pulse rose to 160 and the temperature 102°. Death took place from tuberculous diarrhea. In the second case the physical signs of pericarditis were present and, as the heart was laboring, some fluid was evacuated. No bacilli were found in this by microscopic examination, but a guinea-pig inoculated with it died with cheesy tuberculous pus at the point of inoculation. Death took place with Cheyne-Stokes breathing. No tubercle bacilli were found in the sputum at any time. The autopsy showed a typical case of tuberculous pericarditis.

Cardiac Lesions in the Negro.—Dr. Frank Jones of Memphis, Tenn., read a paper on this subject. Dr. Jones said that contrary to the usually accepted text-book opinion the most common cardiac lesion in the negro is not mitral regurgitation, but aortic regurgitation. A venous hum is heard much more commonly in negroes suffering from anemia than is the case with white patients. Mitral regurgitation is seen with reasonable frequency, but it is not nearly so frequent as aortic regurgitation, nor does it occur so often as aortic stenosis. Often in cases of mitral regurgitation there is no previous history of rheumatism.

Etiology of Aortic Lesions.—Dr. Jones said that the most active factor in the production of aortic disease in the negro is undoubtedly syphilis. On the other hand there is no doubt that among them active acute syphilis has more to do with the production of mitral regurgitation than has acute rheumatism. In the negro it is not an uncommon thing to find precocious syphilitic running its course very rapidly. The three usual stages of syphilis are compressed into one. Periods of the disease are suppressed and lesions of the different stages follow one another without intervals. Another striking peculiarity is the fact that negroes do not seem to recover completely from the disease. Mercury relieves most of the symptoms, as it does in the white, but relapses are more frequent and periods of the disease supposably past for good recur and run an obstinate course. Gonorrhea and tuberculosis cause mitral lesions in the negro.

Pericarditis in the Negro.—The most common cause of pericarditis in negroes is undoubtedly pneumonia. Pneumonia is, as is well known, quite fatal in the negro race. The complication of pneumonia and pericarditis is extremely common. The absence of pericarditis in the negro during an attack of pneumonia is more the exception than the rule. This pericarditis often becomes purulent and is not infrequently entirely missed by the attending physician.

Treatment of Pericarditis.—Dr. Frank Parsons Norbury of Jacksonville, Ill., said that the essential basis of the treatment of pericarditis must be absolute rest. After the first stage of pericarditis patients are apt to suffer from little inconvenience and so this rule is often violated. A bland and unirritating diet is required and milk forms the best. In severe cases an absolute milk diet is needed. Hemmeter describes a sudden death after a full meal during the course of a pericarditis. Dr. Norbury has seen two cases of pericarditis diagnosed as gastritis.

Absorbefacients.—The best internal remedy to produce absorption is undoubtedly the salicylates. In all cases of rheumatic pericarditis, in all cases of pericarditis, rest must be insisted upon. The affection invariably improves if the patient is kept absolutely at rest. Diuretics may also be employed for their absorbefacient effect and the bowels must, of course, be kept thoroughly open. Blistering may have a good effect in starting the absorption of the fluid from the pericardial sac.

Pain.—Pain is usually the most striking symptom and the one that most urgently demands treatment. Cold applications are often very soothing. An ice-bag to the chest or a coil of cold water may be employed. Cold seems also to arrest the effusion. When cold is not borne well, heat often answers the same soothing pur-

pose. Hot cloths may be placed on the precordium and frequently changed. A blister often serves a useful purpose in allaying pain.

Restlessness and Insomnia.—Where this is a prominent symptom, the bromides must be freely employed and the principal doses of the remedy given in the evening, for it is most needed at this time. Sleep is very important in these cases, because the more rest the patient gets the less work the heart has to perform. Where the restlessness is due to irritation of the overworked heart, a combination of digitalis and strophanthus will often prove effective. A diuretic that relieves the pressure on the circulation will sometimes prove useful in these cases and for this purpose calomel in small doses and continued for a long time is the best.

Mechanical Interference.—There should undoubtedly be more frequent tapping of the pericardial sac in order to relieve the laboring heart by the removal of the effusion, which causes so much interference with its function. Whenever dyspnea becomes a prominent feature of the case and a small rapid pulse develops, with physical signs of a large amount of effusion, the pericardium should be tapped. Brentano insists that there is more danger in this operation than is usually thought. According to him the heart is always pushed up toward the chest-wall and may be punctured. He prefers to resect a rib and to puncture the pericardium, after the sac has been freely exposed. The operation of tapping the pericardium has been done a number of times, however, and only very rarely has there been any serious results.

Causes of Pericarditis.—Dr. Delancey Rochester of Buffalo said in opening the discussion that the two principal causes of pericarditis are undoubtedly pneumonia and rheumatism. In serious pericarditis the result is often fatal, not so much because of the pericarditis itself as of the existence of a general toxemia which caused the pericarditis and also involvement of the heart muscle. One of the most prominent symptoms of pericarditis and the one that most frequently calls attention to the condition is excruciating pain. This may take the form, in mild cases, of substernal distress. The toxemia is the important condition to treat. In most cases of pericarditis the kidneys, the skin and the bowels should be freely employed to eliminate the toxins present in the circulation. The best remedy for the pain and for the encouragement of absorption is undoubtedly leeches. They are entirely too little used at the present time.

Recognition of Pericarditis.—Dr. James J. Walsh of New York said that the occurrence of cases even in the practice of careful diagnosticians in which the pericarditis was recognized only postmortem shows how easy it is for this affection to be missed. As a rule, the physical signs are so characteristic that it would not be missed if the slightest suspicion of its presence is aroused. The important thing, then, for the practitioner is to know what symptoms should call his attention to the pericardium. The most prominent sign is the pain. This occurs in the majority of all the cases. Tenderness is a still more common symptom and is present practically without exception. The touch of the fingers, or the stethoscope over the precordium, is complained of at once. After the tenderness the feature that should arouse suspicion is the fluttering wave-like character of the heart impulse present in all thin patients. If the patient is put in a good light, this may even be seen. The precaution of examining in a good light should not be neglected. When the apex beat can not be felt, the patient, instead of being asked to sit up and then stoop far over as is sometimes the custom, should rather be asked to turn over on the face and by pulling up the knees somewhat assume the genupectoral position, not a difficult matter, when the apex beat can always be felt. While in this position the distance between the apex beat and the outer border of heart dulness can be determined and, when this is larger than normal, it constitutes the best sign that we have of effusion in the pericardium.

Pericarditis and Peculiar Symptoms.—In a certain number of cases pericarditis is associated with peculiar reflex symptoms. The phrenic nerve passes along over the pericardium and interference with it may cause pain at the insertion of the diaphragm, especially behind the sternum and along the ribs and at the lower dorsal vertebræ behind. The winding of the recurrent laryngeal nerve around the great vessels at the upper part of the pericardium sometimes gives occasion for symptoms along its distribution. The pains may be referred to the shoulder, the neck, the arm, and even the jaw. A condition of spasm may develop owing to connection between the recurrent laryngeal nerves and the pharyngeal muscles. These spasms may arise whenever an attempt to swallow is made. Even the sight of food may cause pharyngeal contractions. A true hydrophobia has been noted, as the result of a large pericardial effusion.

Rheumatic Pericarditis without Arthritis.—It is well recognized now that rheumatic endocarditis and pericarditis may occur and run their course without any arthritic symptoms. The pericardium and endocardium, especially the ends of the valves really represents joints in the tissues, that is, places where tissues are discontinuous in order to be able to move easily on one another. Such tissues are always covered by serous membranes and partake of the character of joints, whether they be in the limbs or in the trunk. That rheumatism should affect such joints without affecting other joints is not surprising, since monoarticular rheumatism is not infrequent.

Recurrent Laryngeal Paralysis.—Dr. Herrick of Chicago said that the recurrent laryngeal nerve may be affected by pericardial effusion and by consequent adhesion so as to produce paralysis of the vocal cords. Such recurrent palsy may even take place from dilatation of the left auricle.

In cases of extensive effusion into the pericardium, there is nearly always some dulness to be found.

Surgery of Pericardium.—Dr. Carl Beck of New York said that the existence of adhesions of the pericardium to the heart undoubtedly interfered very seriously with the heart's action. There are certain cases in which the existence of synechia of the pericardium can be definitely recognized. In these cases the adhesions may be freed by surgical interference. Surgery of the pericardium involves no more danger than surgery of the pleural cavity. Abscess of the pericardium should be opened at once and drained. There need be no fear of serious result if patients are not allowed to run down too much before operation. A form of pericarditis that has not been mentioned by the medical men is that in which the rupture of an abscess of the liver takes place into the pericardium.

Symmetrical Gangrene.—Dr. Carl Beck of Chicago reported a case of symmetrical gangrene of the hand. With the X-rays the atrophy of the third phalanges of the fingers could be seen very distinctly. At the same time a proliferation of the bony material of the other phalanges could be noted. The case seems typically one of Raynaud's disease, but the proliferation of bony tissue is a new symptom that has never been noticed before in these cases. When gangrene of one of the fingers set in, amputation was performed and later on the same operation had to be performed on a corresponding finger of the other hand.

Fourth Day—June 7th.

Pseudosmallpox.—Dr. T. J. Happel of Trenton, Tenn., presented a further report of pseudo or modified smallpox. This represents observations made in a series of four hundred cases that had come under the writer's observation since he took up the question of modified smallpox last year. The important characteristics of this disease, which seems not to be true smallpox, are that it is much milder than smallpox, that it runs a much more rapid course, that it is comparatively non-contagious and that many vaccinated persons suffered from the disease within a short time after successful vaccination, while the unvaccinated frequently escaped.

Illustrative Cases.—Dr. Happel described one case in a child, who continued to go to school until the desiccative stage. Though friends in the house acquired the disease, none of the children who attended school at the same time were affected. Dr. Happel saw thirty-five to forty cases of the disease in one day in eight different families, yet found only one of the patients sufficiently ill to be in bed. This was a man who had been vaccinated successfully not long before, while many of the other cases were not vaccinated.

Mildness of the Disease.—In country districts children were often out of school only for one or two days during the period of invasion. As soon as the eruption took place, they felt so much better that they wanted to go to school again. In some districts the disease was so mild as to give much less inconvenience than vaccination. One board of health that considered the disease to be smallpox said it was easier to acquire protection by an attack of the disease itself than by vaccination. Only two deaths took place during the epidemic in Dr. Happel's knowledge. These were said to be due to smallpox. One of them occurred in a very old man, whose kidneys and heart were in a very bad condition. The other took place in an old woman, who drank by mistake a carbolic-acid and chloride-of-potash gargle.

Observations by Others.—Friends of Dr. Happel have reported to him a series of cases which have been under their care suffering from a disease like that so familiar to Dr. Happel. One physician, a member of the Tennessee Medical Association, had seen one hundred and six cases of the disease, only seventy of which occurred in non-vaccinated people. Thirty-six of the cases occurred in patients who had excellent signs of having been vaccinated and most of them within the year. The cases were no severer in the non-vaccinated than in the vaccinated. Soldiers who saw a good deal of smallpox during the war, and some of whom had suffered from the disease themselves, said that the cases around them were not at all like the smallpox they had seen and nursed.

Old and New Smallpox.—Dr. W. L. Beebe of St. Cloud, Minn., said that he had seen two epidemics of smallpox twenty years apart. The latter epidemic is of so slight a type as to resemble chicken-pox more than smallpox. Twenty years ago there was no difficulty as a rule in diagnosticating smallpox. During the present epidemic even those who had large experience with the disease before, often found it necessary to send to the secretary of the State Board of Health. In one case under Dr. Bebee's care, the husband, who had pitted pox before, acquired the disease from his wife, although the sister and child, who had not been vaccinated, did not acquire the disease. The vaccination seemed to modify the course of the present disease very little if at all. Dr. Beebe is not a disbeliever in vaccination, but states the facts of the present epidemic as they have come under his observation.

Sanitation of Smallpox.—Dr. Leroy of Memphis, Tenn., gave some points on the sanitary management of smallpox. For scattered cases he thinks that local treatment with isolation is better than transfer, because of the danger of communicating the disease. Cases are better taken care of by the State Board than by local boards of health, because of the danger of local influence interfering with quarantine. Reports of the disease should be made by telephone, so as to avoid the carrying of infection. All exposed persons should be isolated for a time and not allowed to go around until the symptoms of the dis-

ease actually develop. As a rule, health authorities cannot expect the conscientious support of affected persons and their friends. Formalin disinfection is reasonably cheap and is effective. In old tumble-down cabins, such as one finds in the South, it is impossible to disinfect by formaldehyde gas, because of the number of openings for its escape. In these cases sulphur fumes, if abundantly used and developed rapidly, have been found effective.

Hypodermic Vaccination.—Old, unglycerinated vaccina, may contain a number of foreign micro-organisms and no true vaccine virus. It will then give rise to what looks not unlike a genuine vaccine sore, yet affords absolutely no protection. Dr. Leroy has found that hypodermic vaccination gives less risk of septic infection and, especially in unclean patients like the negroes, is less liable to be followed by complications. The injections should be made into the skin not through it, and the groove of the needle should be held downward. Where large numbers are to be vaccinated, this can be done much more rapidly than by the ordinary method, with much less discomfort, and with much more assurance of success. Secondary infections are preventive to a great extent, and the habit that negroes have of rubbing sputum on the vaccination marks is rendered harmless.

Diagnosis of Mild Smallpox.—Dr. Heman Spalding of Chicago said that the diagnosis of mild smallpox, as in the present outbreak of the disease in this country, presents certain difficulties and yet none that make differentiation of the disease impossible. When the present epidemic began in Chicago, some of the cases were diagnosed impetigo contagiosa, Cuban itch, giant varicella, and the like, but these terms were evidently dictated by the disinclination to call cases smallpox. During the last twenty-seven months there have been two hundred and seventy-five cases of smallpox in Chicago, which began from a pair of negro cases imported into the city with the original diagnosis, varicella.

Characteristics.—None of the cases in the present epidemic were without the characteristic eruptions, though some thirty cases of smallpox *sine eruptione* were seen in 1894. In only one case was there a preliminary erythematous eruption. Only confluent cases gave any mortality. Many cases were modified by vaccination. No confluent cases occurred in persons who had previously been vaccinated. Abortive forms of the disease were seen in those recently vaccinated. The fact that 177 mild cases of discrete smallpox occurred among unvaccinated patients shows how lacking in virulence was the epidemic. Patients invariably feel better after the eruption makes its appearance. The preliminary fever, practically always necessitated confinement to their houses, while the relief felt during the eruptive stage gave occasion for patients to go out to work. Two hundred and sixty-one of the patients had never been successfully vaccinated. Of those who had been vaccinated, the actual occurrence of true vaccinia could be doubted in many cases. Mild cases were kept in the wards alongside severe cases, and yet never contracted the disease a second time, nor a severer form of the disease. One case that was diagnosed chicken-pox by four doctors was declared by the board of health smallpox and was proved to be such by the fact that three relatives, who had been exposed, developed hideously confluent forms of true smallpox. There can be no doubt that the disease now under observation is true smallpox and not any intermediate disease.

Smallpox and Chicken-pox.—Dr. Frederic Leavitt of St. Paul, Minn., said that the average mortality of the present epidemic has been less than two per cent. No other infection has proved so mild. Undoubtedly in many cases it gives less trouble than vaccination. There is no question, however, of its being true smallpox. In certain doubtful cases, where supposed chicken-pox was not strictly quarantined, serious cases of true smallpox developed as the result of contagion.

Smallpox.—Dr. Bracken of St. Paul, Minn., said that the mistakes of diagnosis in smallpox are often not due to entirely disinterested motives. Dr. Bracken has had under treatment six hundred and sixty-two cases of the disease. Only ten of these occurred in people previously vaccinated, and out of these only two had been recently vaccinated. One patient, with pits from an old smallpox thirty-five years ago, contracted the disease again. Dr. Bracken saw several successful cases of vaccination after previous variola. In one case a young woman, who had had very mild smallpox, had herself vaccinated in order to get evidence for a damage suit to prove that the smallpox diagnosis was wrong. She suffered, however, only from modified vaccinoid. The length of time during which vaccination affords protection is very different in the individual cases. One woman in Paris was vaccinated successfully every six months for three years.

Pseudosmallpox.—Dr. Bailey of Kentucky said that Dr. Happel's position with regard to pseudosmallpox was unfortunate and hurtful. Whatever the disease may be in Tennessee, when it crosses the line it becomes smallpox in Kentucky. Smallpox may run a very mild course, as it is doing generally in the present epidemic and yet be true smallpox with occasional cases of the virulent affection occurring, to show that it is true smallpox.

Intermediate Diseases.—Dr. James J. Walsh of New York said that in the last fifteen years we have come to admit the existence of a third disease, German measles, between measles and scarlet fever. Recent observations point to the fact that there is perhaps a fourth disease in this group. We know how hard it is to recognize mild smallpox from severe chicken-pox. The Vienna school of dermatologists, the best diagnosticians in cutaneous diseases in the world and with ample opportunities for the study of both diseases, have not as yet entirely given up the

idea that the two diseases are closely related to one another and are not essentially distinct. It would not be surprising, then, if perhaps a third disease, sharing the characteristics of smallpox and chicken-pox should be found to exist. Dr. Happel's observation seems to point to some such conclusion. Certainly the only thing that can be done is to encourage careful clinical observation of the disease, during the frequent opportunity for investigation furnished by the present epidemic.

Pseudosmallpox and Vaccination.—Dr. Happel in closing the discussion said he wished it to be distinctly understood that he is no opponent of vaccination—on the contrary he is one of the strongest advocates in Tennessee of the protection it affords. By calling it pseudosmallpox he does not mean to convey the impression that the disease should not be segregated, nor isolated, but he considers that in Tennessee, at least, physicians are in the presence of a mild or modified form of smallpox that requires further study in order to determine its exact position as a contagious disease. If it is given some such name as pseudosmallpox this will encourage further careful observation in the matter.

BOOK REVIEWS.

Whitman's Orthopedic Surgery. For Students, Practitioners and Specialists. By Royal Whitman, M.D., Adjunct Professor of Orthopedic Surgery, New York Polyclinic, Instructor in Orthopedic Surgery in the College of Physicians and Surgeons, and Chief of Orthopedic Department in the Vanderbilt Clinic, New York. Lea Brothers & Co., Philadelphia and New York, 1901.

This is a branch of surgery which lends itself with the greatest facility to pictorial illustration. The diseased conditions are visible and not less so are the therapeutic means and results of treatment. We have, therefore, in this handsome volume an abundance of diagrams, a wealth of photographic reproduction and a good supply of skiagrams. They all add clearness to the text which of itself reflects the clarity of the author's views of the practical questions and situations with which the book is replete.

Especially full and satisfactory are the discussions of the prevention of the deformity of Pott's disease, the "exercise treatment" of lateral curvature of the spine, and the management of that large class of deformities and disabilities less interesting to the general reader and practitioner, but still of great importance, which have their origin in nervous lesions. The author has not lost sight of the fact that this special branch of surgery is largely preventive, that its patients are chiefly infants and young adolescents and that its best achievements are not so often found in successful operating as in the strictly orthopedic procedures which foresee the evils of postponement and secure ultimate good results by an alliance of mechanical skill with growth and the natural reparative forces. It may be said that no subject in the range of orthopedic surgery has escaped without due practical attention. Of especial value are the authoritative sections devoted to Coxa Vara and The Weak Foot.

A Text-Book of the Practice of Medicine. By Dr. Hermann Eichhorst, Director of the Medical Clinic at the University of Zurich. Authorized Translation from the German. Edited by Augustus A. Eshner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. With 84 illustrations. In two volumes. W. B. Saunders & Co., publishers, Philadelphia and London, 1901.

Professor Eichhorst, though the head of a great Swiss clinic, is one of the most practical and conservative of German clinicians. His larger work on special pathology and therapeutics is one of the standard authorities for consultation all over the world. His shorter text-book on the practice of medicine is in German one of the most popular books for ready reference in medicine for students and practitioners. The book deserved well to be translated and the translation is well done.

Notwithstanding the number of text-books on medicine that we already have, this book deserves a place in American medical literature, because it reflects very thoroughly yet briefly European medical practice. Few text-books of medicine are so complete and so well done in every department. The paragraphs on treatment are especially satisfactory and always suggestive. As a rule, they represent Professor Eichhorst's own clinical experience.

The illustrations are many of them pictures observed by the author himself and they add not a little to the value of the book. The editorial work has been well done. Occasionally Professor Eshner has done well to suggest certain practical points in therapeutics that the experience of physicians outside of the Continent has made worthy of trial. The work is in two handy volumes and will make an excellent authority for consultation, especially for those who are not in a position to follow German medical literature in the original.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

A System of Physiologic Therapeutics. Edited by Dr. S. Solis Cohen. Vol. I. Electrotherapy by Dr. George W. Jacoby. 8vo, 242 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Appendicitis, Its Pathology and Surgery. By Dr. C. B. Lockwood. 8vo, 286 pages. Illustrated. The Macmillan Company, New York.

ORIGINAL ARTICLES.

THE IMPORTANCE OF A RECOGNITION OF THE SIGNIFICANCE OF EARLY TUBERCULOSIS IN ITS RELATION TO TREATMENT.[1]

BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, NEW YORK.

IT would seem almost unnecessary to emphasize the importance of making an early diagnosis in tuberculosis. To reach a positive conclusion before the disease has caused extensive lesions or seriously impaired the patient's resistance, or before a simple tuberculous deposit in the lungs has become complicated with secondary infection, is obviously a matter of vital importance to the patient. The records of the autopsy-table and the clinical results noted in truly incipient cases where intelligent and radical measures are applied at once, bear ample evidence to the curability of the incipient stages of the disease, while the terrible fatality of the malady after it has seriously impaired the general health needs no comment.

The results obtained at sanatoria have demonstrated not only that the disease is curable, but that it is curable in direct proportion to the stage at which the treatment is applied. The published reports of the Adirondack Cottage Sanitarium show conclusively the value of an early diagnosis. During the years 1897-98-99, of 113 incipient cases, 82, or 72 per cent., were discharged from the institution apparently cured, while of 151 advanced cases only 27, or 17.8 per cent., recovered, and not one of 59 far-advanced cases was discharged apparently cured.

No doubt the diagnosis of incipient tuberculosis presents often many difficulties. Our standard as to what constitutes a truly incipient case should constantly be made more rigid. Persistent slight cough, with loss of flesh and strength, a slight afternoon rise of temperature of one-half to three-quarters of a degree, and constant lassitude, are symptoms which even without any appreciable signs on physical examination, point in many cases to incipient tuberculosis, but which are too often disregarded. Perhaps too much importance is attached to the absence of any normal signs in the chest, and the case is not looked upon as being tuberculosis until the stethoscope gives ample evidence of its presence in the lung; and yet we know that often all the rational symptoms of the disease are present long before the lesions can be detected by physical examination; that miliary tubercles in the lung may give no appreciable signs; and that physical examination cannot be expected to detect the onset of tuberculous infection in central portions of the lungs, or in the glands and deep tissues and organs of the body. Search for the bacillus should be begun early and persisted in as long as any doubt as to the diagnosis exists. Much time and zeal is wasted in the meaningless task of counting the number of bacilli as a guide to prognosis which would be employed to better advantage for the patient in searching for the bacillus while the symptoms are still obscure. The microscope has been of invaluable aid in the diagnosis of tuberculosis, and when the bacillus is found there is no appeal from its decision; but its absence from the expectoration is not necessarily a conclusive criterion. We should not wait always until the tubercle bacillus is found, for it is of immense advantage to the patient if a conclusion can be reached before it appears in the expectoration, as this does not occur until ulceration of the tubercles has already taken place. Too much stress is laid upon the negative results of the microscopic examination, and much valuable time lost on this account. I repeatedly see cases, beginning with hemoptysis and some failure of health, even when slight afternoon temperature is present from any cause, with or without some physical signs in the chest, where the patient is assured that he has not tuberculosis because one or two examinations of the expectoration have failed to reveal the presence of the bacillus.

In the great majority of cases a consideration of the history of the case and a careful study of the rational signs, with a thorough physical examination of the chest, and a microscopic examination of any sputum obtainable, aided by a careful X-ray examination of the patient when required, will enable the physician to make an early diagnosis. If this cannot be done the tuberculin test has many times helped me to reach a conclusion, and either to reassure the patient or to insist on prompt and radical measures of treatment without loss of time. It is not often necessary to use it, but its value lies in the fact that it is most applicable and will demonstrate the presence, and give corroborative evidence as to the absence, of a tuberculous process in the body in just that class of incipient cases where the usual methods of diagnosis fail. It is in the detection of incipient tuberculosis that its best field of usefulness lies. Where any marked degree of fever is present it is less reliable, as the balance of the heat-regulating centers in such cases is already disturbed and the injections may cause fluctuations of temperature which may be misleading. In my experience it has proved generally reliable and free from any ill effects, and

[1] Read before the Association of American Physicians, Washington, May 1, 1901.

has many times enabled me to insist on prompt and radical measures of treatment months before a conclusion as to the true nature of the disease could have been reached by the usual methods. Its more general application in the place of the waiting policy so generally resorted to will in skilful hands warn the patient and the physician of the real danger and save many lives.

A diagnosis of truly incipient tuberculosis would no doubt be oftener made if its all-important bearing on the treatment was more fully appreciated. My experience in going over the histories each year of many hundreds of consumptives would lead me to believe that the grave responsibility which rests on the physician of detecting the disease in its very earliest stages and the significance of doing so in relation to successful treatment are not generally realized. In the great majority of cases valuable time (many months and even years) is allowed to elapse since the first symptoms of ill health appeared before the patient is told the nature of his disease and urged to adopt radical measures for its arrest and cure. Too often he is not told that he has tuberculosis until he can no longer be deceived. His disease is labeled grip, pleurisy, bronchitis, or malaria; he is informed that the blood came from his throat; until persistence of the symptoms, rapid emaciation, constant cough, hectic fever and sweats, make the true nature of his malady but too apparent, when he is advised to give up his occupation and make a change of climate or seek admission to a sanitarium, only to find that the proposed change is of little avail, or that he has applied too late and cannot be taken at an institution.

Many patients who come under my observation far advanced in consumption have been advised months previously that they were not *ill enough* to make a change of climate and surroundings necessary. In spite of every effort much difficulty is experienced in securing incipient cases for admission to the Adirondack Cottage Sanitarium, and 70 per cent. of applicants give histories which make it evident that some of the symptoms of tuberculosis have been present for from one to three years before they were advised to apply for admission. The examiners for the Massachusetts State Hospital for the Treatment of Tuberculosis refuse about 60 per cent. of all who apply, because their disease is too far advanced. About the same proportion is refused in our examinations at Saranac Lake, and of the remaining 40 per cent. admitted not more than one-half are really incipient cases.

Recently a gentleman, a member of this Association, who for years has given his services as examiner in a large city for the Sanitarium, made to me the rather discouraging statement that not a single really incipient case of tuberculosis had ever been referred to him for examination. These facts do not look as if the profession was very generally impressed with the importance of an early recognition of the disease, or its significance in relation to treatment.

The real difficulty which often exists in making an early diagnosis, the desire of the patient to remain at home as long as possible, the apparently mild character of his indisposition, and the disinclination of the physician to alarm him, explain in a great measure the waiting policy which is so often adopted. The difficulty of making a diagnosis is not always responsible, however, for many cases show from the first symptoms which are almost unmistakable, such as hemoptysis, enlarged lymph-nodes, dry pleurisy, ischiorectal abscess, or night sweats, but are allowed to continue for months and sometimes for years without a knowledge of the true nature of their disease, or urged to adopt the necessary measures for its arrest and cure.

The increased opportunities for observation enjoyed by physicians in charge of sanatoria have already made very evident to them the significance which the early recognition of the disease bears to its successful treatment. At the Massachusetts State Hospital for the Treatment of Tuberculosis, patients are admitted from the list of those who have passed the necessary examination, not in the order in which they have applied, but according to their physical condition, the most favorable cases for treatment being taken first. Dr. Weicker, at the Berlin Congress, stated that, at his Sanatorium near Goebersdorf, of the cases which he classes as "in initial state," and which were discharged as cured in 1896-97-98, 97 per cent. were still at work on January 1, 1899, while, on the same date, of those who when they entered the Sanatorium, were classed as "advanced phthisis with destructive process," and discharged during the same years, 77 per cent. were dead.

From my own experience I foresee that although the open-air method and sanitarium régime have given renewed hope in the treatment of this fatal malady, the results obtained in the many institutions now projected or already built will be disappointing unless the all-important bearing of an early diagnosis in the successful treatment of the disease is more generally realized.

A STUDY OF SOME COMPLICATIONS AND SEQUELÆ OF TYPHOID FEVER.

BY H. A. HARE, M.D.,

OF PHILADELPHIA;

PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE AND PHYSICIAN TO ITS HOSPITAL;

AND H. R. M. LANDIS, M.D.,

OF PHILADELPHIA;

ASSISTANT IN THE OUT-PATIENT DEPARTMENT OF THE JEFFERSON COLLEGE HOSPITAL.

(Concluded from page 989.)

Respiratory System During Convalescence.—Abscess and gangrene of the lung are occasionally met with at this period of the disease but are extremely rare. Remlinger did not meet with either condition in the autopsy records of 315 cases. A pleurisy, typhoidal in origin, some-

times occurs to which we have already referred. Stenosis of the larynx is reported by Eshner.[24] The stenosis first manifested itself by hoarseness and the difficulty in breathing which rapidly became marked. The condition gradually subsided leaving some edema of the arytenoids. Lockard[94] reports a case of laryngeal stenosis due to abscess of the arytenoid. An extremely rare complication was seen by Dettling and Remlinger,[92] a pneumothorax following pulmonary infarcts. During the stage of convalescence the danger of tuberculosis is imminent when owing to the lowered vitality of the patient a tubercular infection may be planted upon a pneumonic patch or a latent nodule may break down. Milian[95] states that dulness, rough inspiration and râles at the right apex are not unusual in typhoid fever. This may give rise to a diagnosis or a fear of tuberculosis but he asserts that the condition always disappears. Prolonged irregularity of fever with some pulmonary signs are not infrequent, and may also give rise to a fear of tuberculosis but the fear is he thinks usually baseless.

Circulation During Convalescence.—Myocardial changes are not of unusual occurrence in typhoid fever, at least histologically, and are found in nearly all fatal cases. Guyard[30] states that the myocarditis may be benign; may be fatal in its results; or it may give rise to chronic changes after recovery from the fever. Remlinger in a study of 315 autopsy records found the cause of death to be due to degenerative changes in the heart muscle in 11 cases. Burland[96] studied the vascular system in 250 convalescent soldiers. He found in a large proportion of them that the pulse was rapid, small and compressible with signs of early cardiac dilatation. He mentions one man apparently convalescent who suddenly collapsed from acute heart failure. At autopsy the left ventricle was found to be dilated and the muscles thin and soft. Phlebitis, particularly of the femoral veins, may occur at any time, is far more frequent as the fever declines, and during the stage of convalescence than at other times. An unusual complication of the veins is reported by Munro and Workman[39] where as a result of thrombosis of the mesenteric veins gangrene of the large and small bowel, above and below the ilio-cecal valve, followed. Gangrene as a result of arteritis is not common. While it usually occurs during the active period of the disease or early during the convalescence, it may occur very late, as in a woman reported by Ansen[78] who developed gangrene on the eighty-eighth day. Arteritis may also give rise to a hemiplegia. In a case reported by Osler in *Studies No. III.*, the stroke occurred in the tenth week, and Ansen[78] reports one as late as the ninth week.

Blood During Convalescence.—Thayer[47] in an extended review of all cases of typhoid fever treated in the Johns Hopkins Hospital, 829 in number, shows that the secondary anemia which develops during the height of the disease gradually disappears after the fourth week. The fourth week marks the lowest point in the great majority of cases. In cases of short duration, however, the fall may continue during the first week of convalescence. The average loss of red cells is about 1,000,000 per c.mm. The hemoglobin is equally reduced but its return to the normal percentage occupies a longer time than the regeneration of the red cells. The colorless cells, which are usually diminished in number may, in the later stages of the disease, especially in severe forms, show an increase. Of the individual white cells the lymphocytes, both large and small, are increased during convalescence. The polymorphonuclear neutrophiles are diminished and the eosinophiles may be increased during convalescence.

Alimentary System in Convalescence.—Flexner[47] in writing of unusual forms of typhoidal infection believes that a localized cholecystitis or infection of the gall-bladder will eventually be recognized. Camac believes that infection of the gall-bladder by the bacillus typhosus occurs from the intestinal tract, and that the bacilli may lie dormant, causing no disturbance for long periods, even years. If, however, gall stones are present or there is mucous formation, a cholecystitis may develop with ulceration and perforation. Horton Smith[53] points out the analogy existing between the urinary and gall bladder. In the latter, just as in the former, typhoid bacilli may gain entrance without causing any disturbance. Smith is of the opinion that these secondary infections are brought about by the transference of the bacilli through the blood stream. That the typhoid bacillus is not the only cause of cholecystitis during typhoid fever is shown by bacteriological examination. Marsden[58] in reporting a case of cholecystitis caused by the bacillus coli communis states that this germ is not an infrequent cause of the condition. Cushing[98] has reported five cases of post-typhoidal cholecystitis in which pure cultures of the bacillus coli communis were isolated. Richardson[99] has also stated that the frequency of its presence seems to have been an important bearing in producing gall-bladder infections.

Camac has collected 115 cases from the literature. The time of the infection could not be determined in 82 of these cases but in those in which it could be definitely ascertained showed the greatest frequency between the tenth and thirtieth day. From a study of isolated cases reported from time to time it would appear that the infection is more often a complication than a sequel. Camac reports ten cases occurring as a complication and one as a sequel. Gillies[56] among 215 cases observed cholecystitis in five cases, one being of the ulcerative type the result of gall stones. Ryska reports three cases of cholecystitis in two of which there was involvement of the intrahepatic bile passages with some enlargement of the liver. One of his cases was almost chronic in type, lasting for forty days. Camac believes that relapse may be brought about

by reinfection from the gall bladder before immunity is fully established. Mantovani[100] reports a case in which there were two relapses each relapse being attended by jaundice. In one of Ryska's cases there was a relapse with a return of jaundice and evidences of another attack of cholecystitis, and in a case reported by Hamilton[51] cholecystitis followed a second relapse on the seventy-second day. J. W. Smith[58] met with a case of acute infective cholecystitis in a soldier suddenly seized with pain in the right hypochondrium and vomiting. It is possible this was a case of typhoid infection limited to the gall-bladder, although there was no bacteriological examination made. Still, in view of the fact that enormous numbers of the soldiers in South Africa were stricken with typhoid, it is strongly suggestive of a localized infection.

The symptoms of cholecystitis on which Camac lays most stress are the early appearance of pain in the region of the gall-bladder, tenderness on pressure and a tumor. Jaundice is of doubtful value in cholecystitis depending as it does on blocking of the common duct by a stone or inflammatory occlusion. He also places very little reliance on chills, sweating and temperature. Ogilvie[101] reports four cases of typhoid fever associated with jaundice. In one case the jaundice was present from the onset, in another it developed on the fourth day; both of these cases had marked tenderness over the region of the gall-bladder. The jaundice disappeared as the disease subsided. If this jaundice was the result of typhoidal cholecystitis it is certainly a very early manifestation. In another case the jaundice existed for four weeks prior to the attack of typhoid and was probably catarrhal. In a fourth case reported by Ogilvie jaundice developed during the second week. He gives no details of the case. Janeway[7] has seen no case of typhoid fever complicated by catarrhal jaundice.

Cholelithiasis is a sequel rather than a complication and may give rise to symptoms at widely varying periods from the attack of typhoid fever. Camac reports six cases occurring among the cases in the Johns Hopkins Hospital in *Studies No. III.* The earliest time following the attack of typhoid fever was three months; the latest, twenty years. The relationship between cholecystitis and cholelithiasis is an interesting one. In the first place it has been proved bacteriologically that the typhoid bacilli are in some instances undoubtedly the cause of gall-stones. Owing to their tendency towards clumping they offer a suitable nucleus about which the cholesterin crystals may form. Horton Smith[4] is of the opinion that an inflammatory condition of the gall-bladder arising after typhoid fever in which pure cultures of the typhoid bacilli are found is brought about first by the formation of gall-stones, and that the cholecystitis is secondary. Where the cholecystitis occurs as a complication the gall-bladder may become primarily inflamed without the presence of gall-stones. Cases are reported in which during an attack of typhoid fever individuals have died from ulceration or perforation of the gall bladder as the result of gall stones. In these cases it is highly probable that the gall stones were already present, and by their presence excited the typhoid bacilli to activity. Marsden's[55] case had a perforated gall-bladder in which no gall-stones could be found but usually the suppurative and ulcerative cases are associated with stones. It is quite clear that the evidence of gall-stones may be latent for prolonged periods and doubtless in a great many cases their presence is never detected. Their presence is usually discovered by the ordinary manifestations of gall stone colic except in those cases associated with cholecystitis followed by perforations which of course are more severe in character.

Involvement of the liver itself, aside from some enlargement secondary to gall-bladder infection, is rare. Remlinger noted abscess of the liver three times among the autopsy records of 315 cases. Royer[142] has reported two cases which he designates as the hepatic form of typhoid. In both cases during the second week the temperature fell to normal, there was vomiting, bilious in character, and hiccough. In this connection may be mentioned a subdiaphragmatic abscess found during convalescence from typhoid fever. R. Caton[143] and W. T. Thomas, who report the case, are unable to account for the origin of the abscess. The pus contained typhoid bacilli.

Genito-Urinary System During Convalescence.—While numerous reports have of late appeared with accounts of pyuria or an acute cystitis due to typhoid infection there have been very few in which the condition has become chronic. Young[47] in an extensive report of a case of chronic cystitis following typhoid states that he has been able to find but two recorded cases in the literature. In the acute cystitis of typhoid the urine is acid and irritation symptoms are unusual, the patient in the chronic cases being unable to say when the trouble began. Curschmann[102] reports these cases coming on during defervescence and convalescence and lasting from six weeks to four months. Two cases of hemorrhagic cystitis are reported by Vincent[144]. Both occurred during the third week and showed large numbers of typhoid bacilli. Horton Smith[4] in the Goulstonian Lectures for 1900 states that bacilluria exists in about one out of every four cases of typhoid and that cases so affected are as a rule rather more severe. While it may occur at any time during the course of the disease it rarely occurs before the third week and is even more often delayed until convalescence. He believes that the condition is brought about by bacilli excreted by the kidney from the blood and multiplication in the bladder. The urine under these circumstances is acid, turbid in appearance with a shimmer when shaken, and contains ranging amounts of albumin. Pyuria may be associated with this condition. Garnier and Lardennois[140] report a case of pyonephrosis, the pus

showing the typhoid bacilli. Nephrectomy was first done, and later the kidney was removed, death occurring shortly afterward.

Secondary infection of the testicle and epididymis occurs in the great majority of cases in convalescence. Do[103] reports 39 cases with the following observations: Suppuration occurred in one-fifth of the cases; the testes and epididymis are oftenest involved together, occasionally the epididymis alone; bacteriological examination showed all of the simple cases and most of the suppurative cases to be due to the typhoid bacilli. The onset may be manifested by sudden pain and fever, or may develop insidiously. In the simple cases atrophy may take place while total destruction of the testicle in the suppurative cases is not unusual. Kinnicutt[145] from a report of two cases and a study of the literature finds that while orchitis and epididymitis most often occur as sequelæ some 16 cases are reported as arising during the course of typhoid fever. While sometimes secondary they are usually typhoidal in origin. The lesion, is as a rule, unilateral and involves either the testicle or the epididymis or both and not infrequently the cord. Suppuration occurs in 25 per cent. of all cases but destruction of the entire testicle or atropy are of infrequent occurrence. Constitutional disturbance is very slight. J. W. Smith[58] observed orchitis as a complication in a few instances, but in none of them did suppuration occur. Trasburger[104] mentions a case in which multiple abscesses appeared during convalescence with location of one of them in the right epididymis.

Nervous System During Convalescence.—By far the commonest manifestation of nervous disorder during the stage of convalescence is neuritis, either multiple or localized. The neuritis manifests itself by pain, loss of power and muscular atrophy, the condition being amenable to treatment and usually ending in recovery. Among the convalescing soldiers in South Africa a very common complication was what was termed "tender toes." J. W. Smith[58] states that these cases are characterized by exquisite tenderness of the pads and balls of the sole of the foot unassociated with redness or swelling. Gillies[56] also noted this condition in a number of cases reported by him. J. W. Springthorne[105] who has also seen service in South Africa, reports an officer who during convalescence had numbness of his feet, inability to raise the toes, inability to evert the feet, dragging of the toes and atrophy of the leg muscles. Other cases also occurred, according to this officer, who attributed the trouble to the use of the "puttes" which were tightly strapped about the legs. In this way it is probable the peroneal nerve became pinched near the upper end of the fibula.

Hysteria occasionally develops during the convalescent stage, and in ten cases reported by Osler[47] it occurred in each instance in a male. In a case reported by Jacquet and Lacarre[106] the hysteria was associated with hemihyperesthesia, vesical paresis and polyuria.

Meningitis, the result of infection of the meninges by the typhoid bacillus, is reported by A. Hoffman[107] and a second instance by Laignel-Lavastine.[147] In discussing meningitis, the result of typhoidal infection Hoffman believes that where there is no evidence of the presence of a purulent exudate the condition is caused by the presence of toxins in the meninges. Paralysis of the acute ascending variety (Landry) has been observed in five cases by Ganiez[100]. He also reports five cases, one his own, in which symptoms of both a spinal and peripheral lesion existed. This last type was characterized by an acute ascending paralysis, with partial recovery, followed by hyperesthesia and atrophy of the muscles (does not mention whether this case occurred in convalescence). According to Joseph Baylock[109], psychic disturbances occurring during convalescence are always of a graver import than those arising during the height of the disease. The disease often leaves a greater or less intellectual enfeeblement, sometimes a slight disturbance of intelligence with partial or total loss of memory. There may be an ambitious delirium, actual mental aberration and various forms of chronic insanity. Mania is by far the most frequent manifestation and is usually of short duration. In an epidemic of typhoid among the insane George Boody[41] states that complete recovery from insanity occurred in ten cases while a temporary improvement took place in a few others.

Hubbel[17] states that complications involving the eye seldom develop during the height of the disease and that this is especially true of oculomotor palsies and optic nerve atrophy.

Typhoid Spine. (Spondylitis typhosa).—Mention of this condition was made in the previous essay. The condition was originally described by Gibney who believed it to be due to a perispondylitis. Osler[110] reported three cases and as the result of an analysis of the symptoms believes it is a form of neurosis, in some cases at least, on the ground that prolonged periostitis without suppuration is unlikely. Instances have since been reported by Quincke[111], Könitzer[112] Schaptz, Lovett and Withington[59]. The symptoms may be delayed for some weeks after apparent recovery from the disease. The first manifestation is severe pain in the lumbar region of the spinal column, a rise in temperature and intense pain on movement of the trunk or pressure over the spinous processes. More or less pronounced paresis of the lower limbs follows, with, in some instances, shooting pains. The patellar reflexes are ultimately lost and there may be incontinence of urine and feces. In the case reported by Lovett and Withington the reflexes were exaggerated and ankle clonus was present. This case would also indicate that there may be organic changes, as was asserted by Gibney, for, there was distinct swelling over two of the lumbar vertebræ. In distinction from Pott's disease, with which spondylitis may be confused, suddenness of onset taken in conjuction with a recent attack of typhoid fever is important.

Unusual Complications.—Addison's disease first appearing during the fifth week of typhoid fever, is reported by H. W. Evans[114]. The patient was a girl aged seventeen who was seized with vomiting attacks and tachycardia during the fifth week. A week or ten days later pigmentation of the skin appeared above the pubes, extending to the nipples and axillæ. Cardiac asthenia and emaciation steadily progressed and in two months from the onset of the symptoms the patient died.

Exophthalmic goiter in a male appearing during convalescence is reported by Benoit[115]. During the first week of convalescence tachycardia set in, followed in about two weeks by tremor of the hands. Still later exophthalmos and enlargement of the thyroid gland were noted. The symptoms were invariable and at times the patient became very emotional. It should be stated that his grandmother and an aunt had goiter.

Suppuration of the thyroid gland was observed by Schudmak and Vlachos[116]. At the onset of the attack of typhoid fever slight enlargement of the thyroid gland was noted. A month from the onset the gland became enlarged, tender, and the skin over it reddened. Examination of the blood showed a progressive leucocytosis. Incision of the gland revealed pus from which the typhoid bacilli were grown in pure culture. They formed the conclusion from experiments that the typhoid bacillus is capable of producing pus, except the most virulent which act too rapidly, and that the leucopenia of typhoid fever does not depend on the virulence of the germs but on their localization in the chief sites of leucocytic formation. A second instance of suppuration of the thyroid gland is reported by R. J. Godlee.[148]

Wind swallowing is reported by Reuter-Sonderburg[117]. A woman during the third week was seized with sharp pains radiating from lower end of sternum, dyspnea and great distention of stomach. She went into collapse and unconsciousness. On passing a stomach tube an odorless gas escaped but no dilatation of stomach was present. This procedure had to be repeated at intervals to avoid collapse. Distention was attributed to the swallowing of air owing to presence of mucus in mouth.

Relation of Epilepsy to Typhoid Fever.—L. P. Clark[118] examined several hundred epileptics for the purpose of finding what influence typhoid fever had in the etiology of epilepsy. He takes a view opposite to that held by Dide as in only one instance was he able to find that the attack of typhoid fever had any bearing on the epilepsy. Gillies[56] observed typhoid fever twice in epileptics. In one case the number and severity of the fits increased as the fever subsided; in the other no fits were observed while the case was in the hospital.

Relapse and Recrudescence.—A relapse may be of two kinds, first, that which occurs after a definite period of apyrexia, and, second, as "intercurrent relapse," so called because reinfection occurs when the temperature has nearly reached normal only to rise again. The former is by far the most common form. The frequency of relapse varies largely with different authorities. Osler in *Studies No. III.*, found 10 per cent. among 829 cases, while Blackader among 100 children, noted it in fifteen instances. While a recrudescence is usually attributed to some indiscretion in diet, or to excitement or to the so-called "bed fever," cases are occasionally seen in which it is difficult to distinguish between recrudescence and a true relapse. Osler[47] in his recent report cites a case illustrating this difficulty. One relapse is the rule but cases not infrequently are seen in which two or more are noted. Atkinson[119] reports a man who following a period of pyrexia on the fifth day had a relapse lasting twenty days; this was followed by another period of apyrexia when on the eighty-seventh day he had a second attack lasting for thirteen days. Thus the entire attack extended over a period of one hundred days. J. W. Smith[58] found disturbances of temperature as convalescence was coming on, or had been established, extremely common in the military hospitals of South Africa.

Second Attack of Typhoid.—Reinfection with typhoid fever a considerable period after complete recovery is established is extremely uncommon, but Nest[120] investigated 118 cases with reference to recurrence and found 10, giving a percentage of 8.5 per cent. This, however, seems somewhat too high and would probably be greatly reduced were larger numbers of cases investigated. Among his ten cases, the recurrence occurred at periods varying from 45 years to 7 months. Curiously enough, of the two cases which died, the greatest time had elapsed since the first attack, namely, 45 and 25 years. One case which had an attack after an interval of 24 years recovered. Etienne[20] reports a remarkable case in which three attacks occurred in a woman. The first in her 27th year; the second in her 44th year, and the third in her 57th year, the patient surviving. He also gives details of 35 cases of double attacks. Larquier,[63] writing of typhoid fever among the insane, reports ten cases of recurrence.

TREATMENT OF DIABETES MELLITUS.[1]

BY ABRAHAM MAYER, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO LEBANON HOSPITAL.

MUCH has been written on the causation of diabetes mellitus and more on the treatment of this disease, but until we have found the exact etiological factor or factors in its production our treatment must be influenced by the symptoms of individual cases.

Of course, when syphilis and functional nervous disorders produce a glycosuria the treatment is simple enough; such cases form rather a small percentage of those who suffer from this malady. By far the larger number are those in which no cause is known. Each case must, therefore, be specially considered and the treatment instituted according to whether it be a mild or a severe type of the disease.

The treatment accordingly should be directed toward (1) eliminating the amount of sugar in the urine and blood, (2) maintaining the nutritive equilibrium of the patient or even increasing it, (3) maintaining or increasing the function for assimilating carbohydrates, and (4) the prevention of complications. To accomplish these several objects the treatment resolves itself into dietetic, hygienic and medicinal. Naturally much depends upon the type of the disease, and the class of patients we have to treat. It has been my custom in treating this affection to divide my cases into the mild and severe forms, whether the origin be pancreatic, neurogenic, gouty, or bacterial. How do we differentiate these types?

By the mild form is understood those cases of glycosuria in which by the removal of carbohydrate food the urine loses its glucose entirely, or it is reduced to an infinitesimal amount, without much influence on the weight of the patient. These cases are generally seen in persons past middle life, although sometimes in youth also.

In the severe type the sugar does not disappear from the urine, notwithstanding the entire withdrawal of carbohydrates. There is great wasting; acetone, diacetic acid, even B-oxylbutyric acid are frequently present, generally with an increase of urea, ammonia, etc., in the urine. Such cases are not infrequently seen in young individuals and among the poor and laboring classes.

There is some tolerance for carbohydrates in all forms of the disease, more, of course, in the mild than in the severe type. As it has been repeatedly proven that in a mixed diet (proteids, fats, plus carbohydrates) the carbohydrates not only produce by their oxidation animal heat and energy, but also prevent destructive disintegration of animal tissue, it is a great error to exclude carbohydrates entirely from the food of diabetes, except for the purpose of diagnosis or in the beginning of dietetic treatment.

Voit has shown, and it has been repeatedly verified, that in order to maintain nutritive equilibrium an average adult requires at least 2,500 kilo-calories of food daily (carbohydrates, proteids and fats.) A kilo-calory is the amount of heat required to raise one kilogram of water one degree Centigrade. In speaking of calories in this paper, I refer always to the large or kilo-calory. It is known that 1 gram of carbohydrates represents 4.1 calories, gross; 1 gram of proteids represents 4.1 calories, gross; 1 gram of fats represents 9.3 calories, gross.

A diminution in the amount of any one of these foods must be replaced by a corresponding amount of calories of either of the other two foods.

As the prime object in the treatment of a mild case is to diminish the hyperglycemia and glycosuria, we must begin by excluding carbohydrates from their food, replacing them by other forms. It is best to do this gradually taking at least three or four days to come to the point of total exclusion, and keeping this up for three or four weeks until the urine becomes free from sugar. In this way not infrequently the tolerance for carbohydrates becomes re-established and maintained, and the function for assimilating them increased, so that after several weeks or months of treatment these patients receive quite a liberal quantity of carbohydrates in their food, amounting to as much as 80 to 100 grams daily, which may be cautiously increased.

This method of dieting in the mild cases may be sufficient to keep the urine constantly free from sugar, the patient maintaining his nutritive equilibrium and nitrogenous balance; he may even increase in weight. It stands to reason that such patients must be kept under observation and, of course, the same method of dietetic regime repeated in case of the reappearance of sugar in the urine.

In those cases in which a small quantity of sugar still persists with this method of dieting, and where the nitrogenous elements in the urine are increased, it will be necessary to greatly reduce the proteids with the carbohydrates, substituting for them their caloric value in fats. Frequently the carbohydrates and proteids may be advantageously replaced by milk. Many diabetics, both in the mild and severe type, will assimulate a large quantity of lactose without showing much if any increase of sugar. In fact, milk forms an important factor in the diet in the majority of my cases. Should this method of treatment, together with judicious medicinal treatment, fail, the case is undoubtedly a progressive one and must be classed in the category of the severe form.

[1] Read before the Section on Medicine of the New York Academy of Medicine.

In the severe type I am extremely cautious about the dietetic treatment, and, when the urine reacts to Gerhardt's test, a strict rigid diet is to my mind a grave error and very injurious. But when Gerhardt's test is negative, when the quantity of urea is normal or not much increased, and when the patient is still in the prime of life, a strict, rigid diet should be enforced in the beginning, providing the loss of weight is not too great and nitrogenous elements, such as albumens, etc., are absent in the urine. In many of these cases there is an increased nitrogenous metabolism and here the aim should be not so much to diminish the sugar excretion as the nitrogenous waste and the production of diaceturia. This may be accomplished by the administration of carbohydrates and fats and diminution of the proteids. While such cases are under diet it is important that the sugar excretion should be estimated daily, and the general condition of the patient, his weight, the urea and if possible the ammonia excretion must be carefully watched. Any decrease in weight and presence of diacetic acid in the urine would be an indication to increase both carbohydrates and nitrogenous foods at once. Briefly stated, in diabetes of very severe type fats may be allowed *ad libitum*, proteids, and carbohydrates, in the shape of starches and bread, in moderate quantities.

The question of food, its quantity and kind, is a troublesome subject for the physician; for, while it may be a comparatively easy matter in hospitals and private clinics to measure out and weigh the exact quantity of food diabetics must receive and be guided in this by the excretions measured and analyzed daily, in private practice this is almost impossible. For this reason it is well to formulate briefly the caloric values of the most important foods so that a diet table may be quickly drawn up, taking into consideration of course the caloric value lost by the excreted sugar.

Referring to the tables of Rubner, it is seen that individuals of different weight and occupations require a different quantity of calories per kilogram as follows:

TABLE I.

Daily Allowance for Individuals With Easy Occupation or Doing Moderate Work.

Weight	Calories
80 kilograms	2,864 or 35.8 calories to 1 kilogram of weight
70 "	2,631 " 37.6 " " " " "
60 "	2,368 " 39.5 " " " " "
50 "	2,102 " 42.0 " " " " "
40 "	1,810 " 45.2 " " " " "

TABLE II.

Daily Allowance for Individuals Doing Laborious Work.

Weight	Calories
80 kilograms	3,372 or 42.2 calories to 1 kilogram of weight
70 "	3,094 " 44.2 " " " " "
60 "	2,792 " 46.5 " " " " "
50 "	2,472 " 49.4 " " " " "
40 "	2,129 " 53.2 " " " " "

Bearing these in mind it is quite easy to remember that one egg represents about 80 calories; lean beef or fish, as many calories as its weight in grams; very fat beef or mutton, three times as many calories as its weight in grams; butter, eight calories per gram; wheat bread, two and a half times as many calories as its weight in grams, 50 per cent. of its weight being carbohydrates; good gluten bread two or three times as many calories as its weight in grams, 30 per cent. of its weight being carbohydrates; alcohol, about 7 calories per gram.

The caloric value of few other articles may be referred to in any of the recent works on this subject. Thus the whole diet question can be systematized easily. I refer to the following two tables giving briefly the diet and the bill of fare for a day of two diabetic patients of different type and weight.

Example of a Rigid Diet for a Day for an Individual Weighing 60 Kilograms and Requiring 2,368 Calories.

250 grams of	white fish	à 3	calories per gram	= 750	calories
100 "	boiled mutton	à 3	" "	= 300	"
100 "	lean ham	à 4	" "	= 400	"
50 "	cheese	à 4	" "	= 200	"
5 eggs, each		50	" "	= 400	"
				2,050	calories
Add for oil on salad, asparagus, cucumbers, spinach, or cauliflower				300	"
Total				2,350	calories

A bill of fare from the above example might be made up as follows:

8 A. M. One cup of tea with saccharine; 3 eggs and 50 grams of ham for dish of ham and eggs.

10 A. M. One cup of bouillon with 1 egg.

1 P. M. One cup of clam broth; 250 grams fried white fish; dish of asparagus or spinach with French dressing; 100 grams roast lamb with mint sauce; salad with oil and vinegar; 25 grams of cheese; demi-tasse of black coffee.

7 P. M. Three scrambled eggs; 50 grams of broiled ham; salad; 25 garms of cheese; one cup of tea with saccharine.

10 P. M. One dozen small clams or oysters on shell.

Example of a Mixed Diet for a Day of an Individual Weighing 7 Kilograms and Requiring 2,630 Calories.

30 grams of	cheese	à 4	calories per gram	= 120	calories
100 "	smoked tongue	à 4	" "	= 400	"
100 "	veal	à 1½	" "	= 150	"
50 "	ham	à 4	" "	= 200	"
200 "	pompano	à 2	" "	= 400	"
2 eggs, each 80 calories				= 160	"
				1,430	calories
Add for butter and oil on salad				350	"
" " 1 pint milk				350	"
" " vegetables and bread				500	"
Total				2,630	calories

The bill of fare from the above example might be divided as follows:

8 A. M. One cup of coffee and milk with saccharine; 25 grams of wheat bread and butter; 50 grams of ham.

10 A. M. One cup of bouillon.

1 P. M. Six oysters or clams on shell; dish of soup with asparagus tips; 200 grams baked pompano with lettuce; 100 grams roast veal; dish of spinach; 20 grams of cheese; 25 grams of gluten bread; 1 baked apple.

4 P. M. One cup of coffee and milk with saccharine; two raw or soft boiled eggs.

7 P. M. One cup of hot milk; 100 grams of smoked tongue; 100 grams of cauliflower with butter sauce; lettuce; 10 grams of cheese; 20 grams of gluten bread and butter.

The amount of carbohydrates in the portions of bouillon, oysters, clams, asparagus, spinach and cauliflower in the rigid diet list is so small that it need not enter into the calculations of diet, which ought to be changed daily. A glass of Rhine or Moselle wine may advantageously be taken with dinner and supper, the caloric value of which will also help to compensate for that lost by the excreted sugar. Patients undergoing a rigid diet suffer most from the exclusion of bread. This article cannot be replaced by any other article of food although I have found that a few walnuts may serve here. They are very palatable with steaks or chops. Good gluten bread contains at least 30 per cent. of carbohydrates, while almond and aleuronal breads are not palatable unless they contain a large percentage of wheaten flour.

Medicinal Treatment.—There is no subject in the vast domain of medical literature which shows such discrepancies as to the value of drugs as those which have been used in the treatment of diabetes. Where a dietetic treatment removes the hyperglycemia and glycosuria medicinal treatment is not indicated except to correct a faulty stomach or sluggish bowels. Depending on the type and apparent origin of the disease there are some drugs which have a beneficial effect on the excretion of sugar. Among such I will mention opium, arsenic, and the bichloride of mercury.

I use opium for its beneficial effects on thirst and for its general effect on the patient's physical and mental condition. It frequently improves the assimilation of food and allays nervous irritability and often the annoying pruritis. It diminishes the quantity of urine and hence the frequent micturition. It has a decided effect on bolemia for it is often observed that many diabetics consume enormous quantities of food. I have frequently found almost a specific effect from the use of this drug in diabetes associated with neurasthenia, in individuals deeply engrossed in business with its attendant worries. The dose should be small in the beginning, not more than half a grain three times a day, given about an hour or an hour and a half after meals. To get its full effect it may have to be increased to three times this amount. It is a well-known fact that the tolerance for opium and its alkaloids in diabetes is very great. Nevertheless, it must be used cautiously and its constipating effects overcome by cascara or other laxatives.

In severe cases which show Gerhardt's reaction it should never be used on account of the danger of impending coma; nor must it be continued for any length of time in any case.

In the severe type of the disease I have found but little effect from arsenic. In the mild cases it frequently increases the limit of assimiliation for carbohydrates, diminishes the glycosuria and acts as an excellent tonic, especially in those patients who are very anemic and who have had the disease for a long time. In conjunction with diet, or even after a diet and opium treatment, it has given me gratifying results. I employ but two preparations, Fowler's solution and the bromide salt. The latter given in doses of $^1/_{30}$ grain to $^1/_{10}$ grain three times a day in much water after meals.

There are a certain class of diabetics in whom the disease begins about middle life or before. Individuals with an excess of adipose tissue, good livers, who consume great quantities of wines, etc. They exercise but little and hence rapidly take on flesh. The disease commences not unlike an acute infection. Shortly before the outbreak of glycosuria they suffer from malaise, lassitude, cephalalgia and constipation, all symptoms akin to those due to bacterial invasion or ptomain poisoning. When the disease manifests itself the percentage of glucose is found to be very high, and patients rapidly show the effects of a toxic disease. In such cases I feel justified in claiming for the bichloride of mercury a certain, perhaps a specific action in the reduction of sugar and amelioration of symptoms. This fact I pointed out several years ago. The mercury should be given on and off for a period of ten days every month, commencing with $^1/_{12}$ of a grain three times a day and rapidly increasing the dose to $^1/_6$ of a grain three times a day after meals. Usually the teeth and gums of these patients are well preserved and mercury has no effect on them. I have never seen any symptoms of mercurial poisoning when the bichloride is given in the way indicated. Even if the sugar is not entirely eliminated from the urine the patient is restored to a better state of health with entire abeyance of toxic symptoms.

Hygienic Treatment.—The relief of mental anxieties and worries is a *sine qua non* in the hygienic treatment, for it is well known that emotions or nervous shocks aggravate the symptoms decidedly. The patient's surroundings must be made as cheerful as possible and everything done to lighten professional, business and family cares. It is well for the practitioner to dissuade the patient's mind from the gravity of his disease. To him a glycosuria is not so significant a term as diabetes mellitus. The patient must be warmly clad, both in winter and summer, and must keep his skin moist and active by warm baths. Cold plunges and sea-baths ought not to be taken; carbonic-acid baths are very invigorating.

While muscular exercise undoubtedly diminishes the excretion of sugar in nearly all cases, fatigue must be avoided. When conditions are such that exercise cannot be indulged in, massage is indicated; it improves assimilation and promotes a healthy metabolism.

I do not believe in a specific virtue of the

waters of any of the spas, but they certainly do correct many a faulty stomach and sluggish bowels, two factors of prime importance in this disease. At the spas the congenial surroundings, the regular mode of life, the absence of care, etc., all tend to improve the physical and mental state of the patient.

Complications.—Of the numerous complications of diabetes I will briefly mention diarrhea, tendency to suppuration, phthisis, gangrene and coma. As diarrhea frequently follows a constipation, the latter condition must be avoided. Persistent diarrhea often of tuberculous origin must be treated by a mixed diet, opium, iron and washing out of the intestines. The tendency to suppuration shown by cellulitis and furunculosis is met by diminution of the hyperglycemia and glycosuria and antiseptic local medication.

Phthisis, a very common complication, is the cause of death in about 25 per cent. of the cases. It is, therefore, very important that a diabetic patient should carefully avoid all risk of tuberculous infection. If phthisis should arise a sojourn to a milder climate is advisable, and large quantities of fatty foods with some alcohol must be given.

In gangrene the dietetic treatment must be enforced and the gangrenous parts treated with dry dressings and according to modern surgical principles.

In severe cases of diabetes, which show a marked reaction with Gerhardt's test and evidence of B-oxybutyric acid, the danger of coma is imminent. Such patients must be treated by the allowance of a liberal amount of carbohydrates, especially levulose, vegetables and bread. They should drink a great quantity of water, especially the alkaline waters; acids are to be avoided. In these cases milk should be the article of diet. Medicinally patients ought to have enormous quantities of carbonate of soda, 100 to 150 grams daily, and must be kept quiet and avoid all excitement, exertion and exposure.

When coma has set in, blood depletion followed by intravenous injection of 1 per cent. sodium bicarbonate in a normal salt solution should be used. From one to two liters of this solution may be injected in a short time as practised by Lepine. It is always safer to anticipate this complication than to treat it when it arises.

CUTANEOUS MANIFESTATIONS IN DIABETES.

BY S. SHERWELL, M.D.,

OF BROOKLYN, N. Y.;

PROFESSOR OF DERMATOLOGY IN THE LONG ISLAND HOSPITAL MEDICAL COLLEGE, etc., etc.

To enumerate all the cutaneous manifestations in the glycosuric or diabetic patient, considered either as coincidental or etiological, would, as I believe, make it necessary to give nearly a full list of the primary and to some extent of the secondary lesions of skin affections. I must naturally confine myself to those occurring most frequently and to those that are in my opinion not only of the greatest frequency, but of importance also. I will endeavor at least to do so in the order of their relative grave significance.

First of all, then, I would name the generalized xeroderma prevailing in the large majority of cases, in which this glycosuric condition or diabetic disease exists. It is a xeroderma of the functional variety, that coming on relatively suddenly in adults or others, and not one congenital, as in the organic form of this affection, in which cases there is ordinarily great diminution, or almost total absence of the glandular elements of the skin. This dry condition of the skin causes great discomfort, and is ordinarily, though not invariably, attended with distinct generalized pruritus—usually the mucous membranes, oral, buccal, lips, etc., have the same symptoms, at any rate, the first, that of dryness, as can be readily seen, and as readily understood, the skin and mucous membranes being so directly analogous in tissue and to a certain extent in function. So marked is this in some cases that the faucial conditions have not unfrequently led me to the first suspicion of diabetes, the patient being examined for existing or supposed catarrhal conditions. The mucous secretion in those cases of the upper air-passages and mouth has a peculiar and characteristic look difficult to describe; it is gummy, and lies in distinct ridges, resembling nothing so much as the "ribbed sea sand" of the poets, or a beach at low water-mark, with the spume of the sea, thrown up into ridges, here and there. This is purely mechanical, of course, and occurs as a result of the adhesive character of mucus.

I have mentioned pruritus as an accompanying symptom in the condition above; sometimes it seems an entity, or disease of itself, as other clearly-marked and objective symptoms are not present, and at first glance there would seem to be no causative pathological or organic disturbance. This condition of pruritus is most aggravating and distressing. It is often, in my opinion, taken for a neurosis of the skin. This symptom alone being present in an individual, without apparent cause, should excite suspicion and should compel a careful examination of the urine, even when from the general florid health diabetes has not even been suspected.

Probably the next in order of frequency would be the eczematous dermatitic manifestations, occurring in any region of the skin, but most prone to attack flexor surfaces, and more especially the genital, anal, and inguinal regions. These eczemas are usually attended with the fiercest itching and should instantly, and always excite suspicion and lead to careful and frequent examination of the urinary secretion; for often the urine will be found glycosuric at one time of the day, and yet the reaction be absent, or almost totally so, at another hour of the twenty-four, so that the examination of the morning water, the so-called *urina sanguinis*, is not sufficient.

In my experience, I think the symptoms produced by an eczema of this nature, in and around

the genital regions, while not so grave a symptom in significance probably as many others, are more distressing to the patient than any other, and as a rule are those most complained of by him or her. The increased frequency of urination in these cases, the almost inevitable consequent hurry from the frequency with which the act is done, and consequent slight dribbling of urine, over, and about the parts; the drying, and subsequent decomposition of this saccharine urine, will explain this condition in diabetes. Very often the *saccharomycces* and other mycotic parasitic organisms can be found in microscopic examination in full bloom in these situations; and the lesion will furnish a typical picture of the eczema marginatum.

Naturally I have no time or permission to go into therapy in general in these remarks, but would simply state as a matter of experience that cleanliness and antiparasitic lotions of a mild type, frequently employed, are cleaner and much better in the treatment of these conditions than the unguents so often prescribed for their relief. A valuable lotion in my hands has been one of bichloride of mercury, about 1-1000, in a dilute emulsion of bitter almonds, which may also contain a moderate amount of salicylic acid, and resorcin.

Furuncular and carbuncular manifestations are often concurrent as is well known, and are clearly caused by the diabetic state. These lesions and conditions are quite often discretely regional in character. In my experience, the nuchal and gluteal regions show the greatest predisposition. In any patient (certainly any elderly or obese patient, though not confined to them it may be remarked) in whom this condition is manifest or recurrent, the urine should be examined without delay with the same care and frequency as before emphasized. It is astonishing how quickly sometimes this phlegmonous tendency can be controlled, or aborted, on the cause being ascertained and appropriate hygiene, diet, and treatment being instituted. Both in these cases and the eczemas before mentioned, it is something more than carelessness, and approaching criminality, to neglect to try to find out what can ordinarily be so readily discovered by testing the renal excretion.

Erythematous lesions, some evanescent, others of the graver kinds, as erysipelas, are sufficiently common as a result of this glycosuric state, and also gangrene, either relatively superficial or, as after an erysipelas, in the form of gangrene of the extremities, notably the lower.

These are such well-recognized general surgical conditions that they need only to be mentioned as among the lesions produced. I would like to remark, however, that the only times that I have seen erysipeloid manifestations on the fauces and upper air-passages have been in diabetic individuals—at least I could not otherwise class the peculiar inflammatory condition. That condition in those individuals subsided as did other manifestations, under the classical treatment.

A form of vesicular and bullar skin disease, the so-called dermatitis herpetiformis or Duhring's disease has often for one of its etiological factors the diabetic state, although there may, and must be, others that produce this skin affection. I have often found sugar in the urine in cases of this kind, so that I cannot look upon it as a mere coincidence.[1]

As to tumor formations, I do not think one would expect to find cutaneous neoplasms, originated by the diabetic diathesis or state, as ordinarily the conditions prevailing are those of waste, not increase of tissue growth; but there is certainly one, if not two, diseases of the skin of this nature that may be mentioned. They are now quite well recognized. I refer to xanthoma diabeticorum and in my opinion possibly also to blastomycetic dermatitis.

Speaking of the first, the yellow new growth, not so very unfrequently found about the eyelids, and having, as oculists and almost all practitioners know, for its seat of preference and first election, the inner canthus of the upper lid, xanthoma planum, is simulated by growths frequently found in other parts and not unfrequently all over the body in enormous number and quantity in diabetic patients. This peculiar affection, identical in histological character and appearance with ordinary xanthelasma, was first recognized by Mr. Malcolm Morris of London about twelve years ago. Since then perhaps fifty cases have been recorded. I myself have recorded two, the last in the *Journal of Cutaneous and Genito-Urinary Diseases*, September, 1900, for a fuller description of which I refer those interested. The patient had an enormous number of these tumors distributed all over the body and limbs, so that even decubitus in any position was painful, and could not long be maintained, no ulceration occurred. On examining the urine of this patient it was found loaded with sugar, as is usual in those cases. On her being confined to antidiabetic diet almost without other treatment, she was entirely relieved of this affection in a few weeks. On cessation of this diet the eruption reappeared in some degree, again as quickly disappearing under the same régime, this happening again and again and being absolutely commensurate with the degree of obedience of the patient, and thus I think proving in the most distinct manner the etiological connection. The urine tests were effected by the diet in precisely similar ratio. These cases are being now reported with greater frequency, and the same history, or nearly so, applies to almost all.

Of the other neoplasm, blastomycetic dermatitis, I have little personal knowledge, either never having had a case, or else not having recognized it, or else having mistaken it for a verrucose

[1] Of interest in this connection I may mention a case of this kind occurring in a boy, eight years of age, who was under my care last March. I examined his urine carefully, as is my habit in excessively chronic cases of skin disease, and was surprised at the instantaneous, classical, and abundant sugar reaction. Under mild mercurial treatment, alterative and disinfectant doses (as I regard them) of hydrarg. c. cretæ and a decided antidiabetic diet, he became much better, and on examining his urine I now find a comparatively feeble reaction to the test. Is this diabetic or glycosuric state a cause or a consequence? This is the question, and I think a mixed one, for I believe that effect and cause sometimes are difficult to differentiate.

tuberculosis of the skin, which it much resembles. Some of the earliest and best investigations of this peculiar form of skin disease have been made in this country by Gilchrist, Hyde,[1] Montgomery, and others. They find a yeast fungus very plentiful in the tumor and fungations thereof. Curiously enough the urine does not seem to have been examined much, as far as I have discovered in literature. One reason, possibly, why the presence of glycosuria is so relatively infrequently found in the urine of infants and young children may be because of the comparative infrequency of the examination of same. I do not think such examination is often made in the routine practice of the average physician, except during the progress and treatment of the exanthemata, for instance, so few of the degenerative kidney troubles being incident to youth. Therefore transient states of this complication may be often overlooked. As to my own experience I have several times found glysosuric urine in infants (usually those of well-to-do parents), who, from the liberal character of their meals, the abundance, and good serving of same, have been literally stuffed and gorged with the carbohydrates, on the principle that the more they eat, the bigger they will grow. In these cases diminution of the diet, with attention to other conditions, has greatly simplified the treatment and advanced the cure of eczematous and other diseases, and at the same time caused total disappearance of the glycosuric character of the urine.

33 Schermerhorn street, Brooklyn, N. Y.

DIABETES IN SURGERY.[2]

BY ROBERT T. MORRIS, M.D.,
OF NEW YORK.

DIABETES mellitus presents many points of deep interest to the surgeon. Not many years ago patients suffering from diabetes were practically ruled out from the field of surgery, excepting in cases of great necessity. To-day, with our fuller knowledge on the subject, we operate upon diabetics almost as freely as upon normal individuals.

There seem to be three chief reasons why diabetes interferes with a surgeon's work: First, the sugar circulating in the blood is hygroscopic and it draws water from all the tissues of the body until the tissues are actually too dry. This must interfere with the normal process of repair, and it probably does so in several different ways. It may limit the capacity of the leucocytes for furnishing alexins to meet the toxins, and it may interfere with the proper development of new repair cells. It is not improbable that the gangrene following operations in diabetics is due to a blocking of the small lymph-channels with leucocytes, which are unable to travel freely in surroundings devoid of a normal proportion of moisture. I have been watching for an opportunity to make sections in a case of this sort for microscopic study for three or four years, but none of the diabetics upon whom I have operated during this time have suffered from this complication of gangrene, because of the rigid asepsis employed in these cases. Lymph-channels are more likely to become blocked in the course of sepsis. These are the only cases in which I use rubber gloves in operating. If the wound can be kept perfectly aseptic, so that an extensive local hyperleucocytosis necessary for the purpose of meeting bacteria is avoided, then repair goes on quite smoothly.

I have in the hospital at present an old woman with intracapsular fracture of the neck of the femur. She had about eight grains of sugar to the ounce of urine at the time of the operation four weeks ago. The operation consisted in making a large anterior flap of tissues, exposing the neck of the femur and then spiking fragments with a spike driven through the trochanter and the head of the femur. She was put upon dietetic régime for diabetics and the amount of sugar in the urine diminished to about two and a half grains to the ounce, but the patient was not very controllable and complained so much about the diet that we put her back on mixed diet in two or three days and allowed the sugar to return to the proportion of about six grains to the ounce. The large wound healed by primary union and the patient will be ready to leave the hospital in about a week.

A second reason why diabetics require special attention on the part of the surgeon is because the fluids of a wound loaded with sugar are, in all probability excellent culture media and particularly susceptible to the attacks of bacteria. Rigid asepsis is therefore demanded.

A third reason why diabetics interest surgeons is because the anesthetic may precipitate an impending nephritis in kidneys that have become irritable because of the unusual labor involved in excreting sugar. In these cases I use the nitrous oxide and oxygen anesthesia whenever practicable, and in any event avoid the use of ether. Surgeons see a fairly large number of cases of transitory diabetes following injuries of various kinds, and so many of these occur after injuries which would disturb the semilunar ganglia particularly that I was about to propose a very pretty little theory to the effect that diabetes represented a functional neurosis dependent upon a disturbance of large sympathetic ganglia. Dr. Bailey has undermined this theory by showing that in some cases of experimental diabetes in animals the glycosuria continues after excision of the semilunar ganglia. In this connection I would call attention to the fact that Dr. Opie of Baltimore has supplemented the work of Vonuering and Minkowski on pancreatic diabetes by determining that it is only in cases in which the islands of Langerhans undergo hyaline degeneration that we have diabetes associated with pancreatitis.

I had a patient at the Post-Graduate Hospital

[1] Journal Cut. and Genito-Urinary Dis., Jan., 1901.
[2] Read before the Medical Section of the New York Academy of Medicine.

some years ago in whom gall-stones had perforated the common bile-duct and had escaped beneath the peritoneum. An extensive hemorrhage followed beneath the peritoneum, large quantities of bile escaped through the rupture. An enormous abscess followed, so that the peritoneum was apparently dissected away from the pancreas which sloughed. I evacuated the large collection of fluid, removed the gall-stones and the neucrotic pancreas, repaired the bile-duct, and the patient made a good recovery. She afterward came into the office saying that she had diabetes, and I referred her to the medical clinic. We could not find her in time to get notes for this discussion, and to learn of the later history of the case.

About half of the cases of diabetes mellitus that occur as a result of traumatism follow injuries of the head, and almost all of the others seem to follow injuries of the liver, kidney, pancreas, stomach or spleen. Cases of traumatic diabetes are apt to be associated with traumatic neuroses of various kinds, and the glycosuria, while transitory in a great many of the cases, may become permanent. In some cases polyuria exists after sugar has disappeared from the urine, and this seemed to support the theory that the liver and kidney were suffering from a functional neurosis emanating from a common sympathetic center and that disturbance of the kidney lasted longer than the disturbance of the liver; but Dr. Bailey has apparently shown that we cannot look to the semilunar ganglia as a center for the reflex disturbance. The surgeon is sometimes called upon to testify that diabetes has followed a trauma, and it has been discovered on several occasions that the patient was suffering from glycosuria previous to the time of his injury; consequently we have to be on our guard in accident insurance cases, and it is not safe to testify to the character of a so-called traumatic diabetes unless we know the history of the patient in the matter of glycosuria previous to the time of his injury.

MEDICAL PROGRESS.

Basal Fractures.—E. Quénu and R. Tesson, in discussing the symptomatology of antero-posterior paramedian basal fractures of the cranium, bring out the following points. Usually there is deep coma from the onset of the symptoms and often hemorrhage, commonly nasal or buccal, infrequently aural. Such are the only two frank symptoms elicited, because the coma is often a contra-indication to rigid examinations and an internal hemorrhage may be prolonged by it. Pharyngeal ecchymosis has been very rarely reported in literature, either because it was entirely absent or because it was not looked for by the attending physician. Ordinarily fractures of the floor of the cranium must show themselves by indirect symptoms, *c. g.*, hemorrhage, ecchymosis and paralysis, except in those involving the petrous portion of the temporal bone when often the clinical picture is so exact as to permit a diagnosis of different varieties. In certain cases, probably the majority, the splenoidal sinus is opened, whence proceeds the bleeding. Occasionally the foramen lacerum posterius will be invaded and any of the three nerves in it directly or indirectly involved. The other large sinuses of the skull may also be wounded and give rise to fatal intracranial hemorrhage. With an essentially bad prognosis, the diagnosis rests upon uncertain data and often the postmortem examination will reveal the true state of affairs and show the futility of any intervention.

Spread of Yellow Fever.—Previous to the discovery of the fact that the mosquito is the means of conveying the virus of yellow fever, H. R. Carter (*Med. Rec.*, June 15, 1901) collected considerable valuable evidence to show that several days must elapse after a house has been infected before another person will be able to contract the disease. In a number of instances it was distinctly proven that at least ten days must pass after a case of yellow fever has entered a house before the virus will become sufficiently developed to infect a second person, and a subsequent period of from three to six days will elapse before symptoms of the disease are manifested. The first period he calls "extrinsic incubation" and in the light of recent discoveries becomes easily explainable, for it is the time which must elapse from the infection of the mosquito by biting a yellow-fever patient to the time the mosquito becomes capable of communicating the disease to man. From this it follows that when a case of yellow fever develops in a clean house the inmates of this house who leave within a few days may be permitted to go without quarantine detention, for they will not develop yellow fever.

Cause of Cancer.—Since Gaylord published his interesting work in reference to the cause of cancer, much skepticism has been shown in regard to the conclusions which he has drawn. A pure culture of the germ was probably not used in any instance and no attempt was made to recover the organism from the cancer which was produced. S. W. Bandler (*Med. Rec.*, June 15, 1901) points out the evidence which is still lacking to furnish conclusive proof of the germ theory. Blastomycetæ have been found in various chronic affections and their presence in a carcinomatous growth cannot be considered necessarily causal. Although, undoubtedly, the growths which Gaylord produced in other animals were carcinomatous, he used peritoneal fluid and not pure cultures of the organism. He cannot exclude, therefore, the possibility that cancer cells were transmitted. Leopold has shown that from a fresh carcinoma of an ovary a pure culture of blastomycetæ may be obtained which, when injected into a rat, produces a large number of peritoneal nodules (not carcinomatous), but causes death and from these nodules a pure culture of blastomycetæ may be obtained. The

causal relation of blastomycetæ to the growths produced in animals is proven, but the decision concerning the character of the neoplasms and their relation to carcinoma and sarcoma is to be the controversial point.

Evidences of Intellectuality in Brain Morphology.—Comparative anatomy has been frequently made use of in determining the location of various brain centers, and pathological human brains often assist the neurologist in mapping out the cortical areas, but there is still much doubt as to the exact location of many of the sensory and motor centers. E. A. Spitzka (*Med. Rec.*, June 15, 1901) has made a comparative study of the brains of several distinguished persons, among them Dr. Eduard Seguin and his son, Dr. Edward C. Seguin, paying especial attention to the size and development of the island of Reil. He believes that in the anterior part of this area is located the speech center rather than in the operculum, as has been held by some. Furthermore, by comparing the human brain with that of the porpoise, in which animal the sense of hearing is probably more acute than in any other, he believes that the posterior part of the insula shares in its development that of the auditory sense center. The anterior portions of the insulæ in the two brains mentioned above were very noticeably developed and convoluted, so much so that they were protruding more than in ordinary human brains. On the other, a lack of development in the opercula might lead to the same degree of prominence of the insula and thus result from an exactly opposite cause.

Cause of Mental Deficiency.—After investigating 10,000 children, F. A. MacNicholl (*Phil. Med. Jour.*, June 8, 1901) is thoroughly impressed with the belief that heredity plays an extremely important part in determining the mental capacity of our school childen. Of this number 885 showed more or less mental deficiency; 471 were born of drinking parents; 221 were classed as due to heredity and 153 could give no satisfactory information. He was able to trace the family histories of 463 children through three generations and of these 313 had drinking fathers and 51 drinking mothers. Of these children 76 per cent. suffered from some neurosis or organic disease. In 51 families having 231 children with total-abstinence antecedents only 3 per cent. of children were dull and only 18 per cent. suffered from neuroses.

Knee-Jerks in Chorea.—Gordon has called attention to a peculiar knee-jerk which is frequently present in cases of chorea, and A. A. Eshner (*Phil. Med. Jour.*, June 8, 1901) alludes to it as a distinguishing point between this disease and spasmodic tic and athetoid movements. It is not always constant, but when present is probably distinctive. With the patient recumbent and the knee raised, while the heel rests upon the couch and the muscles are relaxed, if the patellar tendon be struck the foot rises, but instead of falling back immediately it remains suspended for a variable time, and then sinks back slowly to its original position. Sometimes only a sluggish descent follows the rise. At other times, as the foot begins to descend, it is caught in mid-air and held for a time or even raised again to a higher level than at first.

Spontaneous Cure of Hydatid Cysts.—W. M. Stevens (*British Med. Jour.*, May 11, 1901), thinks that there are many possible causes for this result. Thus, it may be due to natural death of the parasite—the entrance of bile into the cyst, having a toxic effect upon the parasite; the absorption of the hydatid fluid; inordinate multiplications of the internal brood and lastly, changes in the ectocyst. The length of the natural life of the organism is not known, for active parasites have been found after forty years. Bile does not necessarily cause the death, as the majority of cysts contain no bile. The most widely accepted theory is the absorption of the fluid, but this does not hold good, as many cysts are found to be tense and contain dead parasites. Hydatids of the lung containing daughter cysts are rare, which would prove that the theory of inordinate growth of the internal brood is a wrong explanation of the death of the parasite. The author thinks that the best explanation of the spontaneous cure is found in changes in the ectocyst. The changes are increase of its fibrous tissue or condensation, causing the vessels to become occluded. Dead hydatids are found where the blood-supply is poorest. In many cases there is no puckering or contraction. In hydatids of the lung where the ectocyst is tough, the cyst is small and partly calcareous. Graham also finds in these cases that the tissue about the ectocysts is indurated.

Relationship of Vaccinia to the Inoculated Form of Smallpox in Man.—The transmission smallpox in man to bovines has never given successful results. S. Monckton Copeman (*Brit. Med. Jour.*, May 11, 1901), agrees with Jenner that it is probable that cowpox may have originally sprung from smallpox in man. He says that it is not improbable that the cracked udders of the cow may have been infected by the hands of persons milking the cows, while they still had upon their arms the vesicles of the old form of inoculation smallpox. He found that if he inoculated monkeys with smallpox in a series, he could then produce with virus taken from them, a true vesicle upon the epidermis of calves. Virus taken in turn from the calf's vesicle would produce a true vesicle upon the arms of children, and that there was no "generalization" of the eruption in any of the cases.

Mild Type of Smallpox.—The Dominion of Canada, says F. Montizambert (*Brit. Med. Jour.*, May 11, 1901), is being invaded in some places by smallpox from the United States. So mild is it that in many instances it has been diagnosed as chicken-pox and German measles. The Public Health reports published in Washington show that between December 28, 1900,

and March 29, 1901, there were 11,964 cases reported. Of these, but 157 died. This gives a mortality of 1.31 per cent. It is suggested that the mildness of the type is due to some meteorological condition. There is, as a rule, little, if any, initial fever, a very sparse discrete eruption and no secondary fever. The patient is not usually confined to bed or even to the house and often does not seek medical aid. In many of the lumber camps it is called the "cedar itch." In the States bordering on Canada there have been 4,433 reported cases. That it is smallpox is shown by the fact that it attacks those who have not been vaccinated and those who have not been for some time. Those recently vaccinated are immune.

Mental Fatigue in School-Children.—Through media of dictation, memory arithmetic and combinations JOSEPH BELLEI (*Lancet*, May 11, 1901) studied the effects of the educational system in vogue in Italy as to the amount of fatigue produced in children. The conclusions he arrived at are interesting. (1) No single subject produced any special fatigue. (2) The first hour of lessons is a useful mental exercise, because the children are able during that time to overcome the state of inattention in which they were at the time of coming to school. (3) The morning lessons do not produce great mental fatigue. (4) The midday rest is of great use to the children, because it does not destroy the good effects of the morning's mental exercise. (5) Although the condition of the mind after the midday rest is at its best, after an hour's work the mental fatigue is so great that the worst work of the day is then done. Therefore if the morning's work does not fatigue, it consumes the mental energy of the children in such a manner that they cannot undertake light work in the afternoon without falling into great mental fatigue.

Etiology of Convergent Squint.—The one essential cause of squint is a defective development of the fusion faculty. This is frequently associated with other developmental defects, namely, hypermetropia and congenital amblyopia. Where the fusion faculty is alone defective, or congenitally absent, there is usually an alternating squint with perfect vision in in each eye, says C. WORTH (*Lancet*, May 11, 1901). The treatment of squint should be to prevent the loss of central fixation in the deviating eye; to prevent deterioration of vision in the deviating eye; to train the fusion faculty at the earliest age; and to restore the visual axes to their normal relative directions. Congenital amblyopia and anisometropia predispose to squint by lessening the value of binocular vision. Heredity is a predisposing factor in squint. Of 1,278 cases studied there was a family history in 1,028.

Diagnosis of Functional Disturbance of Kidney.—Functional renal disorders are far more common than anatomical lesions of the kidney. The two best methods for the determination of the former are (1) the ascertainment of the molecular concentration of the urine and (2) the study of the elimination of methylene blue by the kidney after the subcutaneous injection of 0.05 gram. In a healthy individual, according to the observation of ACHARD (*Prager med. Woch.*, May 9, 1901), the drug will appear in the urine in from fifteen to thirty minutes. There may be a delay of several hours under pathological conditions. The total elimination normally is completed in from thirty-five to sixty hours. In desquamative nephritis this period is shortened, while its prolongation to three or four days indicates renal insufficiency.

Local Anesthesia for Abdominal Section.—Little or no shock follows in certain cases where local anesthesia is employed for abdominal sections, says T. H. MORSE (*Lancet*, May 11, 1901). The causes of shock are the anesthetic and the amount of injury produced upon the nerve structure during the operation. There are some patients who are in such a low state of vitality that general anesthesia is impossible and in these local anesthesia is to be advised. No shock followed in five cases of local anesthesia produced by ethyl chloride. Dr. Morse thinks that the pain is less felt when the patient's condition is very grave.

Diminished Subclavicular Expansion in Infantile Pneumonia.—WEILL (*La Semaine Méd.*, May 29, 1901) calls attention to an important early sign in infantile pneumonia, in which condition tubular breathing and râles are so often lacking in the early stages. No matter whether the base or apex be affected, lack of expansion is noticed in the subclavicular region when the child is lying supine. While in pleurisy with effusion deficient expansion may also exist, it is here proportionate to the exudate, and is found either at the base alone or affecting the entire half of the thorax.

THERAPEUTIC HINTS.

Dilatation in Valvular Heart Disease.—From a study of the pathology of residual dilatation of the heart, there are three main indications: To reduce the resistance to systole within the cardiac chambers; to restore or increase the cardiac force; and to remove the accumulation behind the lesion. The first requires rest in bed, or, if this is impossible, in an armchair with the feet down. The second requires careful selection of diet and cardiac and cardiovascular stimulants. The swiftest of these are ether, ammonia, alcohol, and hypodermics of strychnine. Slower, but more lasting, are digitalis and its allies— strophanthus, squill, senega, caffeine, lily of the valley, etc. These drugs increase the force of the systole, lengthen the diastole so giving rest to the ventricle and time for the veins to empty, contract the peripheral vessels, and presently relax those of the kidneys

with free diuresis. But, while waiting two or three days for the diuresis of digitalis, purgation, paracentesis, bleeding or potassium iodide may be advisable. The removal of residual accumulations, dropsy and mechanical congestion, with relief of the alimentary, nutritive and eliminative functions, is greatly favored by purgation. A sharp purge is compound jalap powder, calomel, or calocynth. The catharsis may be attended by much temporary depression, but it is followed by relief of dyspnea and cardiac distress. Rapidly developed anasarca of the limbs may be relieved by acupuncture, but the drainage should not be unduly prolonged. The most urgent cases demand venesection with removal of 300 to 900 c.c. (30 oz.) of blood, but, where there is objection to this, wet-cupping or a dozen leeches over the sternum may suffice. With improvement in the condition, these measures are gradually relaxed, and tonics introduced.—J. Mitchell Bruce in *Treatment in Practical Medicine.*

Scarlet Fever.—In mild cases, the treatment consists of rest in bed, liquid diet, plenty of water to allay thirst and promote elimination of the poison, and a mild cathartic such as calomel. The free use of milk, buttermilk, water and mineral waters lessens the danger of post-scarlatinal nephritis. For a mild diuretic, potassium acetate answers well and may be aided by the citrate or bicarbonate of potash or sweet spirit of nitre. The nose and throat should be cleaned by spray or syringe with a mild antiseptic, such as hydrogen peroxide. A gargle may lessen the danger of ear complications, and in addition the sore throat is improved by a teaspoonful every three hours of the following:

℞ Tinct. ferri chlorid.....gm. 8.0 (ʒij)
Glycerin. } aa.....30.0 (ʒj)
Syr. Simplicis }
Aquæ, q.s. ad.....90.0 (ʒiij)

The temperature may be controlled by lukewarm or cold sponging, or, if the patient is nervous and restless, by acetanilid, phenacetin, or sodium salicylate. A weak heart may require strychnine, digitalis or alcohol. If the kidneys become involved, give warm baths, saline cathartics, milk diet and water with liquor potass. citrat. Keep up counterirritation over kidneys with poultices and mustard, and promote diaphoresis by hot pack or vapor bath. Convulsions may be controlled by morphine, atrophine, chloral hydrate, potassium bromide or chloroform. Urgent symptoms may demand hot mustard baths, with cold affusions or ice to the head, or even venesection. Morphine is the best remedy to control the pain of scarlatinal rheumatism, but sodium salicylate should be given, and the joint wrapped in a glycerin ointment.—F. D. Millard in *Pediatrics,* May 15, 1901.

Meigs' Food.—Soak Russian gelatin or isinglass, gm. 1.3 (gr. xx), in cold water, 240 c.c. (ʒviij, for a few minutes, then boil till the gelatin is dissolved (about fifteen minutes). Add a small teaspoonful of arrowroot first made into a paste with water, then add milk and sugar as follows, and allow to boil for a few minutes. For the youngest children mix two parts of this with one of milk and add two tablespoonfuls of cream and gm. 26.0 (ʒviss) of milk-sugar. For older children from one-half to two-thirds should be milk, to the 50 per cent. mixture, one and one-half tablespoonfuls of cream and gm. 22.0 of sugar being added, and to the two-thirds mixture one tablespoonful of cream and about gm. 16.0 (ʒiv) of sugar of milk. For a child inclined to diarrhea substitute barley or wheat for the arrowroot, and for costive children use oatmeal. Another food useful for indigestion, cholera infantum, diarrhea or dysentery, Meigs made by mixing equal parts of arrowroot-water, lime-water, cream and milk, dose c.c. 60 (ʒij) every two hours. Between the feedings give plenty of cool water with or without brandy, c.c. 4.0 in c.c. 240 (ʒi in ʒviij). After one or two days increase dose to c.c. 90.0 (ʒiij), and gradually diminish the proportion of cream and lime-water till the infant's normal food is reestablished.

Neurasthenia.—Severe cases occurring in women, whether complicated with hysteria or not, are most successfully treated by a strict application of the rest cure. The patient must consent to be the subject of a despotic rule, and peculiar natural qualifications on the part of physician and nurse are essential to the efficient and not disagreeable maintenance of the necessary obedience and cooperation of the patient. Absolute rest in bed, milk diet for a few days, then forced feeding, massage and aloes when needed, constitute the treatment. When somewhat better, an outdoor life without fatigue should be encouraged, with regular graduated exercise and a generous diet. Men seldom submit to the rest cure, but will take up wheeling, golf, rough camping, etc. These occupations should be kept up for a long time. —Sanger Brown in *Medicine,* June, 1901.

Pneumonia.—When cyanosis appears, nitroglycerin, by its vasodilator action, may intensify the capillary paresis, and, though often valuable, may at times be well replaced by diffusible stimulants such as one c.c. (♏xv) each of aromatic spirit of ammonia, compound spirit of ether, compound spirit of lavender and tincture of valerian. If used at all, nitroglycerin requires to be given two or three times an hour. Champagne and dry wines are good in small, frequent dosage. Digitalis and other heart stimulants may be given, but strychnine in full hypodermic doses and the valerianate of caffeine, gm. 0.06 (gr. j), every two hours or oftener, are better remedies. To promote the elimination of toxins administer by rectum and subcutaneously a physiological salt solution, sometimes preceding this by the extraction of 500 c.c. (℥j) of blood from the vein. Finally, the inhalation of oxygen is to be recommended.—R. H. Babcock in *Medicine,* June, 1901.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JUNE 29, 1901.

OUR ANNUAL TETANUS EPIDEMIC.

The time for our yearly visitation of tetanus is at hand. Last year there were not nearly so many cases of the disease as the year before, but still some thirty fatalities were reported in the neighborhood of New York. During the ten days immediately preceding and following July 4th last year there were reported to the Coroner of Cook County, Illinois, which includes Chicago, twenty-nine deaths from tetanus. In the same period of the preceding year only seventeen deaths from the disease were reported. It seems, then, that variations in the mortality of the disease are not due to lessened virulence or better precautions, since practically the same sanitary conditions obtain in New York and Chicago, but probably to local meteorological conditions which encourage or inhibit the growth of the bacillus of tetanus.

It has been claimed that long-continued damp weather especially fosters luxuriant growth of this microbe. Dry, hot weather preceding the Fourth of July means the free play of sunlight on streets and thereby the better disinfection of street dirt, for sunlight is the great natural germicide. Our recent damp and late season, with its noteworthy absence of sunlight, may reasonably be expected to portend a larger mortality than usual from tetanus. It is useless to hope for a limitation of the present insensate celebration of the "Glorious Fourth," on the day itself and for a week beforehand, by fireworks and explosives. The toy pistol and the blank cartridge will continue to have their victims and the physician's only hope lies in his effort to avoid as far as possible the enclosure of the tetanus bacillus in the wounds thus inflicted and the use of prophylaxis against its effects if it should find a lodgment in the tissues.

Dr. Gideon Wells (Medical News, June 1, 1901) emphasized the conclusion that the source of the tetanus bacillus in wounds caused by blank cartridge and fireworks is not something specific to these articles, but is the street dirt that finds entrance into the tissues through the abraded skin. We pointed out editorially last year that the immediate occasion for the growth of the tetanus bacillus in such wounds is the fact that the tissues are seared by the explosive that causes the wound. Beneath the seared surface, walled off from the oxygen of the air, the tetanus bacillus which is absolutely anaerobic in character finds a suitable nidus for luxuriant growth. This fact gives the first indication for the treatment of such wounds. They should be laid thoroughly open. If suppuration occurs, absolutely free drainage should be ensured, for pyogenic bacteria may by their consumption of oxygen in the superficial parts of a wound easily provide extremely favorable conditions for the growth of anaerobic bacteria in the deeper parts.

It must be remembered that the first symptoms of tetanus, as usually described—the slight rigor of the muscles of the jaw, the stiffness of the neck and the tendency to slight muscular spasm—are not signs of beginning tetanus, but warnings of impending death from the disease. The tetanus toxin has already reached its favorite location, the great nerve centers. One of the most serious disappointments of serumtherapy was the failure of the much-vaunted tetanic antitoxin to accomplish in human beings what it had effected in animals. The tetanus toxin becomes firmly lodged in the nerve-cells and cannot be neutralized. Even the proposed method of injecting the tetanus antitoxin beneath the dura, to place it more directly in contact with the nerve-cells, has not met with the measure of success it promised.

The tetanus antitoxin is perfectly capable,

however, of neutralizing the tetanus toxin if it can be brought in contact with it before the toxin becomes fixed in the nerve-cells. To assure this, however, the remedy must be given before any symptom of tetanus shows itself. Whenever, especially in summer, deep or lacerated or seared wounds have had the opportunity of becoming freely contaminated by street dirt, especially by horse droppings, for this material seems to be the principal habitat of the tetanus bacillus, the medical attendant should not hesitate to use antitetanic serum in prophylactic doses. No possible harm can accrue. Tetanus antitoxin has been used in thousands of cases all over the world without a single untoward result or even any unpleasant sequel. On the other hand, the general use of antitetanic serum in the manner suggested would save many young lives that are hopelessly lost if the symptoms of acute tetanus are allowed to develop. In a number of cases undoubtedly the serum would be administered unnecessarily, but the diminished mortality would more than compensate for the exercise of such extra precaution.

"THE OLD MAN OF THE SEA."

In dealing with a problem so stupendous in scope and so hopelessly complicated in its practical application as the tuberculosis question, every advance necessarily broadens the outlook and each new position captured opens up fresh possibilities of attack. The infectious nature of the disease has been recognized for centuries, so that even the older anatomists, like Valsalva and Morgagni, feared to dissect the bodies of consumptives. But it was not until bacteriology had furnished the already existing empirical conclusions with a logical starting-point that efficient sanitary regulations could be made and legal restrictions of sources of peril to the community became feasible. Now that the dangers of close proximity to those diseased in this way are generally recognized and a knowledge of the "infernal machine" represented by each clot of sputum has permeated even to the lower classes, the attention of investigators is being diverted to other elements of the problem. It is not intended to depreciate the importance of what has already been gained or to permit any laxity in the application of all possible precautions, but it is apparent that in some directions, at least, the limit has been or will soon be reached and that, even by the most Draconic legislation, it will never be possible to wholly extinguish this ever-smoldering fire.

The connection between heredity and the phthisical habitus has always been too evident to admit of very serious opposition, but now that researches in other provinces have increased our store of premises it seems but a step to enquire whether, in addition to the now almost universally accepted predisposition, the possibility of an immunity acquired through ancestors may not also be inferred. The notable decrease in virulence in what are, perhaps, next to tuberculosis, mankind's most dreaded scourges, syphilis and smallpox, can hardly be more than partially due to external causes, and the theory of a widespread partial immunization gains color when we consider the frightful ravages produced by these diseases when introduced into virgin soil, such, for example, as has been afforded by the Pacific Islanders. The racial insusceptibility of the negro to yellow fever and the immunity to malaria gradually acquired by whites living in tropical countries are cases in point and if increased power of resistance to such acute diseases is to be borne on through the generations, why not also to a chronic infection like tuberculosis? This is the stand taken by Reibmayr (*Münch. med. Wochenschr.*, Mar. 26, 1901) who believes that the present tendency is too much to place a blind reliance on the hope of enclosing the individual in an artificial prophylactic armor which shall enable him to evade chances of infection, an extravagantly Utopian ideal, instead of fostering the resources of the organism itself and by individual and familiar hygiene promoting and preserving whatever of natural or hereditary immunity we may possess.

Dr. Trudeau's article appearing in this issue is an eloquent appeal for the recognition of another doctrine which has long been preached from Saranac Lake, but is still, judging by the experience of those interested in sanatoria, but little heeded by the general practitioner. Pulmonary tuberculosis, taken in the proper stage and intelligently treated, is a curable disease, and this stage is one that every practising physician can and should school himself to recognize. But once the corner has been turned and the disease from being incipient has become actual, the prognosis is among the darkest in medicine. The gravity of the outlook increases in geometrical progression with the length of time that the enemy has been allowed to operate unmolested. The question is one calling for the rarest good

judgment on the part of the medical attendant, especially, as is often the case, when he is unable to obtain special counsel. Admitting that the diagnosis is frequently among the most difficult, the conscientious man will give his patient the benefit of the doubt, and at once put him in a position to shake off the disease while there is yet time and before this relentless "Old Man of the Sea" has fatally gripped the breast of his victim.

TRAPS AND PITFALLS IN THE PRACTICE OF MEDICINE.

THE practice of medicine has the tendency to bring out whatever is best in a man. Let his natural bent be scientific, literary, humanitarian, philosophic or business-like, he will find an expression for his tastes in his daily work, and his methods will inevitably be stamped by his predominating characteristics. His road to success, however, is beset by dangers that bear no relation to his skill or conscientiousness. They are not the traps of quackery, but the unseen pitfalls into which the most earnest and competent may unwarily slip in their professional zeal.

For instance, the man who neglects to secure his financial position by careful investments, insurance, and prompt collection of his bills, may arrive at the age when he ought to cease active practice, and yet be obliged to continue to make his daily living. Too often keen, able practitioners develop into querulous, jealous, disappointed old men, because they are obliged to compete with the younger men when they ought to have retired with honors.

The neglect of business methods is one of the commonest pitfalls of medical men. An easy-going doctor will let a patient run up a bill for a year or two until it assumes formidable proportions; and the patient, fearing to be asked for it, will call in another man, and intimate to friends who inquire why the change was made that the doctor was in some way at fault.

The honest physician is constantly losing cases that would be of pecuniary benefit, because he refuses to perform some questionable or unnecessary operation, and when another less scrupulous, man consents to do the work, the honest man is made to bear the slur of implied carelessness or lack of skill to hide the real reason why he is no longer that person's physician. It often happens that when a doctor plainly tells the patient that there is nothing the matter with him, or advises treatment that means self-discipline or active exercise, the hypochondriac or lazy invalid will summon a less disinterested man, and cast inuendoes at the former doctor's professional ability.

The possibility of illness and death from infection and the possibility of social ostracism due to deliberate blackmailing or medical scandal are pitfalls that are too well known to need more than a caution by way of comment.

Dr. J. Dundas Grant in delivering his presidential address before the Hunterian Society of London ("Traps and Pitfalls in Special and General Practice") related a number of interesting personal anecdotes of the narrow escapes he had had from falling into some traps, and the experience he had gained by stumbling into others. He thinks that the errors which result from neglect of physical signs are perhaps greater than those that result from defective investigation of symptoms, but the old family doctor, clinging to symptomatology, and the hospital graduate, keen on physical signs, are equally liable to fall into traps by neglecting to combine these methods of diagnosis. But Dr. Grant warns the younger men that it requires as much sympathetic tact as technical skill to carry out a thorough physical examination, as patients are apt to resent what they call being "pulled about." He cites the case where as a young man he was warned that a certain elderly gentleman did not like to have his heart examined, but feeling that the case demanded an examination, he used his stethoscope and was promptly dismissed.

Those who have made the mistakes that Dr. Grant frankly acknowledges, such as diagnosing lumbago instead of aneurism of the abdominal aorta, catarrh of the uterus, instead of suppuration of the Fallopian tubes, hemorrhoids instead of epithelioma of the rectum, and dyspepsia instead of carcinoma of the stomach, will be interested in his description of the pitfalls he learned to avoid through the instructive lessons of physicians whom he called in as consultants.

But on attaining the rank of consultant himself Dr. Grant remarks that he was much struck with the ease with which he seemed to arrive at the diagnosis of the obscure cases to which his friends called him, as contrasted with the difficulties he had had in analyzing his own cases. The conclusion is evident, he remarks, that a man called in consultation in a particular case, seeing it for the first time when its features are well developed, is in a much more favorable position

for diagnosing it than he who has watched its gradual development from the outset, and there is need for the charitable and honorable consideration on the part of the consultant toward the practitioner placed at such a comparative disadvantage. The reverse position, however, may call for charity on the part of the family doctor, who calls a consultant for a single examination of a case when it is too obscure to allow of absolute diagnosis. A few hours or days later the symptoms may have developed so that he reads their meaning plainly, and if he is narrow-minded may utter an unfair opinion of his colleague's judgment.

The traps into which the surgeon may fall, for lack of medical knowledge and those that beset the physician who knows but little of surgery, may be best avoided by taking advantage of the special knowledge of one's fellow practitioners. While the family doctor should emulate the exactness of the consultant, the latter should try at the same time to look at the case from the point of view of the general practitioner; for the traps into which both general and special practitioners are likely to fall are many, the former for want of special knowledge, and the latter for want of general regard to medical considerations.

ECHOES AND NEWS.

NEW YORK.

Medical Society of the State of New York.—Dr. Henry L. Elsner, President of the Medical Society of the State of New York, announces the appointment of his Business Committee for the ensuing year, consisting of Dr. Nathan Jacobson, Chairman, 430 S. Salina Street, Syracuse, Dr. George Ryerson Fowler, Brooklyn, and Dr. William C. Krauss, Buffalo. All letters and inquiries pertaining to papers and scientific communications for the semi-annual meeting to be held in New York City, October 15th and 16th, 1901, and the annual meeting to be held in Albany, January, 1902, should be addressed to the Chairman.

Examinations for State Hospital Service.—At a meeting of the State Civil Service Commission held November 9, 1900, it was decided to accept in lieu of the examination heretofore required by the Commission for the position of physician, first and second grades, (including the position of medical interne in the State hospitals) the examinations for license to practise medicine in this State conducted under the authority of the University of the State of New York, and to enter accepted applicants for such positions upon the eligible list in accordance with the ratings obtained by them in the examination for license to practise. In accordance with this action, an eligible list will be made up after the examination for license to be held in June, 1901, containing the names of persons whose applications have been accepted prior to July 1st. The positions are open to men and women. The salary in most cases is $600 and maintenance. Persons desiring to obtain a place upon the eligible list must file applications on the forms provided by the Commission. Such forms will be furnished on application to Chief Examiner, State Civil Service Commission, Albany, N. Y.

New Sanitary Superintendent for Richmond.—Dr. Theodore C. Walser, one of the oldest physicians on Staten Island, has been appointed sanitary superintendent for the Borough of Richmond. The office was made vacant by the recent death of Dr. John L. Feeney.

Health Official Indicted.—Dr. Obed L. Lusk, Deputy Sanitary Superintendent of the Health Department in the Borough of Queens, was indicted by the Queens County Grand Jury last week on a charge of neglect of duty. The indictment is based on the death of John Charlton of hemorrhagic smallpox at Woodside on May 4th. Charlton's body was left in his apartments, which were in a thickly populated tenement house, for fifty-two hours after his death. Charlton was ill for several days and his case was reported to the health authorities, but he was not removed and died while his wife and children stood around his bed, hungry and ill.

Navy Repulses Health Board.—A sharp conflict took place recently between the officials of the Navy Yard and the health authorities of Brooklyn as to the jurisdiction of the latter over patients suffering with infectious disease upon Federal property. The controversy arose over a case of smallpox which was being cared for by the Navy.

Grip Among Horses.—Although there may be some difference of opinion expressed by veterinary surgeons as to the extent of the peculiar epidemic which prevails among the horses of New York, nearly all are agreed that it is serious and likely to become more so within the next few days. The number of afflicted animals has been placed from 15,000 to 40,000. The disease is evidently of bacterial nature and contagious.

Pure Milk in New York.—The Milk Commission of the Medical Society of the County of New York has just made a public statement of its work and incorporating advice as how to secure pure milk. The formation of the Commission was the outcome of a symposium on milk held over a year ago in which many eminent authorities took part. So much interest was aroused that the Society determined to form a commission that should study the best methods of improving the milk supply of New York. In pursuance of this plan, the commis-

sion held a conference with the milk dealers, invitations having been extended to all the principal dealers in Manhattan and the Bronx. The friendly co-operation of the best dealers was thus earnestly sought, as it was recognized that the subject was beset with difficulties that must be solved, if at all, by the increased attention and labor of those actually concerned in the production and handling of milk as a business. The milk that is daily delivered in New York comes from five States, including thirty-four counties, and comprises more than 1,250,000 quarts. The Milk Commission decided to form a bacterial standard for the purity of the milk submitted to it, as a step in advance for the milkmen. This has been done in several cases with private companies through the country, and it was decided to extend its benefits to any dealer desiring such oversight. The Board of Health looks after chemical composition, and has lately required that milk be not too largely contaminated with bacteria. A circular was drawn up for distribution among milkmen containing the best methods to be employed in producing and handling milk, especially when it has to be transported for a long distance. The rapid deterioration of milk can be much hindered by early preventing its contamination by bacteria present in the dirt of stables, barnyards, upon the cow, and the persons of the men milking and handling the milk. The commission has determined upon a standard of clean milk, and will certify the milk of any dealer coming up to such standard. The work of several competent bacteriologists who have labored for the commission during the past six months, not only examining many specimens of milk, but visiting and carefully inspecting the dairy farms that produce the milk, has shown that milk up to its advanced standard can be sold in this city by observing three precautions: (1) Strict cleanliness, which includes the barns, yards, cows, milkers, and all utensils. Bacteria which get into milk by means of dirt are thus largely excluded. (2) Rapid and sufficient cooling of the milk. The few bacteria that do get in are thus prevented from growing. (3) Thorough icing around the milk until it reaches the consumer. The production of toxins from the growth of bacteria is thus retarded. The milk that reaches the required standard will be certified, as shown by a label. These labels have not yet been given out, as it has seemed best to wait a short interval to see if the standard can be maintained. A dealer may thus have this extra milk for sale, and should get an extra price above his average for it, as his farmer naturally requires more for its production.

Smallpox in New York.—There is so much smallpox in Yonkers that the City Hospital, which is situated several miles from the heart of the city in the woods, is filled to overflowing, and tents which were furnished by the local militia company are being used for the accommodation of patients. Cases of smallpox have also been reported in the Elmira Reformatory, and at the Goshen jail.

PHILADELPHIA.

Typhoid Fever Diminishing.—Health reports for the past week show improved conditions in West Philadelphia so far as typhoid fever is concerned. Investigation of the sewers has been stopped, because of lack of funds. The total number of cases for the city was 61 as compared to 94 the previous week.

State Appropriations for Hospitals.—Much dissatisfaction prevails as a result of Legislative action regarding hospital appropriations. Some of the items have not come under final action, but as matters stand at present the Hospital of the University of Pennsylvania receives no appropriation. Jefferson asked for $300,000 to aid in erecting a new building, but present indications are that only the usual amount for maintenance will be granted, with the possible addition of $100,000. The Medico-Chirurgical Hospital receives the largest amount of any in this city.

Pennsylvania Epileptic Hospital.—This institution, situated near West Chester, received but $2,500 appropriation from the State for the present year. The institution is really a farm where the patients who are able are given light outdoor employment. It is practically the only institution of the kind in the State and, although partly self-supporting, is greatly hampered by lack of funds.

Fourth-of-July Injuries.—Unusual efforts are being made by the authorities to prevent the usual large number of accidents on the Fourth of July. Dealers who sell crackers containing explosives other than ordinary powder are to be apprehended. The Mayor's proclamation also contains the following: "Peremptory orders have been issued to the police to arrest all persons exploding firearms, firecrackers, squibs, chasers, rockets or bombs in the neighborhood of any hospital, home, asylum, or institution for the sick, aged or infirm."

First Cousins May Not Marry.—The bill prohibiting the marriage of first cousins which was recently passed by the State Legislature became a law June 24th, it not having been acted upon by the Governor within the specified time limit. It is stated that Pennsylvania is the eighth State to adopt such a prohibitory law.

Removal of Almshouse.—In pursuance of the plan lately adopted a committee has recently inspected institutions in New York and Boston with the view of removing the Philadelphia almshouse and insane asylum from its present location at Thirty-fourth and Pine Streets. The Committee included Drs. Shoemaker, Tyson, Flexner, Hare, Horwitz, An-

ders, Ashton, and Kirby, as well as several members of the Department of Charities and Corrections. As a result, members of the Board are to make an inspection of the islands in the Delaware River with the view of determining which of them is the most suitable for the new site of the institutions named.

CHICAGO.

Baccalaureate Sermon By Dr. Senn.—Dr. Nicholas Senn delivered the baccalaureate sermon before the graduating class of Rush Medical College of 1901, June 16th. He took for his text the 48th verse of the tenth chapter of the Book of Numbers, "Standing between the dead and the living." He philosophized upon the mysteries of life and death, and then told of Jesus' power over death, as shown in the stories of the restoration of the daughter of Jairus and of Lazarus. He stated that it is the educated, earnest, conscientious physician who is constantly called upon to stand between the dead and the living. Every act on his part is an attack on the death-dealing influences which jeopardize life, and the struggle continues until human aid can no longer compete with the aggressive, relentless foe. Among the learned professions and different avocations of life there is none that requires greater and more careful preparation, and that imposes greater anxieties and self-sacrifice than the duties of the true physician. From the beginning to the end of his professional career he stands guard over the health and life of his clients. He is with them at the moment of their entry into this world, and he attends them until the destroying angel at last defeats his efforts. Like the Great Physician, like Him who is the Resurrection and the Life, he is always found, "standing between the dead and the living." Dr. Senn eulogized the work of physicians in times of plagues and of war, and paid a tribute to the profession.

Important Medical Decision.—Judge Kavanagh recently announced a decision which is of unusual interest to members of the medical profession. In directing a verdict of not guilty in the suit of Mrs. Agnes Mulhern, against the Post-Graduate Medical School and Hospital, the Judge holds that a physician, while performing an operation for the relief of one ailment, is justified in performing an additional operation, if during the first operation he discovers a condition of the internal organs which renders the additional operation necessary to preserve the life of the patient. Mrs. Mulhern submitted herself to an operation for hernia at the hands of Dr. Franklin H. Martin, June 7th, 1897. After the abdomen was opened, the surgeon discovered that other internal organs were diseased. The patient being under the influence of the anesthetic, her consent to a further operation could not be obtained. He, therefore, performed another operation. Later, suit was begun against the attending physicians and the hospital, because of the second operation. The point that the second operation was necessary to preserve the life of the patient, whose general health is now good, was raised in pleas filed for the defendant by attorneys. An appeal was prayed to the Appellate Court from the ruling of Judge Kavanagh. The State Supreme Court, as yet, has not passed on the point directly raised in this case.

New Hospital in Operation.—The Hospital of the Sisters of St. Francis in Evanston has been opened for the reception of patients. No questions will be raised as to race or religion. The Hospital is almost on the borders of Chicago, and is within easy reach of the various suburbs. Dr. J. B. Murphy is the consulting surgeon. The physicians are Drs. E. H. Webster, W. A. Phillips, W. B. Parkes, D. Kaufman, and Dr. Fintzel. Dr. S. V. Clevenger is the consultant on mental and nervous diseases and Dr. James W. Collins on eye and ear diseases.

Wesley Hospital.—This Hospital was opened informally recently at a cost of $210,000. More than one hundred people have made donations toward the building fund, contributing a total of $185,000. Of this amount the largest part has been subscribed by a few men. The Trustees are making an effort to raise the $25,000 balance.

Chicago Medical Society.—at the forty-ninth annual meeting of this Society, the following officers were elected: President, Dr. Christian Fenger; First Vice-President, Dr. Alexander Hugh Ferguson; Second Vice-President, Dr. Hugh T. Patrick; Secretary, Dr. Frank X. Walls; Treasurer, Dr. David Doherty; Necrologist, Dr. W. S. Christopher. The annual address of the President was delivered by Dr. James H. Stowell. The Society now numbers more than a thousand members. Among other things, the President recommended that the Society publish its own proceedings, and avail itself of the valuable fund that would accrue from legitimate advertising, as well as the satisfaction of having the proceedings of each month published promptly. He also recommended that the Society take a more active part in matters of public and professional interest, and, if possible, aid the Commissioner of Health of Chicago in bringing about reforms that directly or indirectly affect the health of the community. He urged retrenchment in the expenses of the Society in order to establish a fund toward securing a permanent home for the Society, and recommended the appointment of a committee on permanent home. At this meeting an address on "The Streptothrix Infections" was delivered by Dr. John H. Musser of Philadelphia, by invitation.

Laying the Corner-Stone of the Senn Hall.—The exercises incident to the laying of the corner-stone of the Senn Hall were held June

19th. The stone block was lowered upon the mortar, and Dr. Senn helped the laborers drag it home. In the hermetically sealed metal box which was placed in the corner-stone were deposited photographs of Dr. Senn and Dr. Daniel Brainard, the Chicago daily papers, the University of Chicago and Rush Medical College calendars, the list of faculty members, and a copy of the *Journal of the American Medical Association*.

Appointment of Dr. Hunter.—Dr. Warren H. Hunter has been appointed County Physician by the Board of Commissioners of Cook County.

To Enlarge German Hospital.—This hospital will be enlarged by a building to cover an additional frontage of 75 feet, and to cost $40,000.

State Board Examinations.—These were held a few days ago by the State Board of Health at the Great Northern Hotel. About 125 candidates for license to practise medicine in the State appeared.

Commencement Exercises of Northwestern University.—The forty-third annual commencement exercises of this University were held June 20th. The Northwestern University Medical School graduated a class of 74 and the Woman's Medical College, 19.

Commencement Exercises of Rush Medical College.—The exercises were held at the Studebaker Theatre June 21st. There were 191 students in the class of 1901 who received the degree of M.D. The Doctorate Address was delivered by Professor Richard Burton of the University of Minnesota. The honorary title of Master of Surgery was conferred on Dr. Nicholas Senn. The award of fellowships and prizes was announced as follows: Fellowship in Pathology, Ludwig M. Loeb; Fellowship in Chemistry, Herbert G. Vaughan; Fellowship in Medicine, Alexander F. Stevenson; Edward L. Holmes Scholarship at Wood's Hall, Martin H. Fischer; Benjamin Rush Medal, Leslie Rutherford; J. W. Freer Medal, Robert J. Gay, Class of 1902; De Laskie Miller Prize, Paul Oliver.

GENERAL.

Tuberculosis Among Samoans.—Commander Tilley, the Naval Governor of Samoa, in view of the alarming extent of sickness, particularly among young children, has suggested that American nurses would find Samoa an exceptionally good field for their humane work. He says that in one respect civilization has worked to the detriment of the Samoans. While they lived without clothing they were hardy and free from sickness, but since adopting clothing they get wet from rain, contract colds, and a number have developed consumption, a disease not known before.

Officers of the American Orthopedic Association.—The following officers of the American Orthopedic Association were elected at the recent meeting held at Niagara Falls: President, H. Augustus Wilson, M.D., Philadelphia; First Vice-President, William J. Taylor, M.D., Philadelphia; Second Vice-President, G. G. Davis, M.D., Philadelphia; Secretary, John Ridlon, M.D., Chicago; Treasurer, E. G. Brackett, M.D., Boston. Philadelphia was chosen as the place of the next meeting in May, 1902.

Medical School Destroyed.—During a recent heavy thunderstorm a bolt of lightning struck the College of Physicians and Surgeons, on Harrison Street, Chicago, Ill. The fire which followed the lightning in a short time destroyed the college building, which is one of the finest of its kind in the West. The College of Physicians and Surgeons is the medical department of the University of Illinois, situated at Champaign. The loss on building and equipment is practically total and will approximate $200,000.

Plague at Hongkong.—The plague has broken out in virulent form at Hongkong, according to recent news, and every port in the Orient is taking protective measures. Two steamers are quarantined at Nagasaki owing to the plague having been brought from Hongkong on them. One is the "Empress of China," the other the transport "Kintuck," upon which a Chinese fireman died of plague. The "Kintuck" has 180 United States soldiers and sixteen officers on board returning from the Philippines. A British steamer arrived at San Diego, Cal., June 24th, having sailed from Hongkong May 16th. Five deaths from plague occurred during the voyage. At Hongkong 542 Asiatics and seven whites have died since the beginning of the year.

London Antivivisectionists.—The activity and bitterness of the antivivisectionists was well shown last Sunday when the annual collection for hospitals was taken up. They had boys posted in front of many churches distributing circulars protesting against the collection as they gave aid to vivisection. The President of the Antivivisection Society, Lord Llangattock, has seen fit to defend this action in the press. The collections, however, were as large as ever, and the Lord Mayor has tactfully calmed the indignant protestants.

Lord Lister's Address on Asepsis.—The notable address delivered by Lord Lister at the opening of two new operating theaters in St. Thomas' Hospital dealt with the progress of surgery and the evolution of antiseptic and aseptic technic. In the new rooms the aseptic system will be used instead of the antiseptic, and, though admitting the good thus accomplished, Lord Lister continues to practise Listerism in the old way and to advocate carbolic immersion of instruments and the use of sprays.

Homeopaths and the Army Medical Service.—There is a good deal of feeling over the fail-

ure of the United States Government to make provision in the army for homeopathic surgeons. Surgeon-General Sternberg, United States Army, is said to be in sympathy with such a movement.

Faculty of Army Medical School.—The following officers have been detailed as members of the faculty of the Army Medical School: Col. William H. Forwood, Assistant Surgeon-General, President of the faculty, *vice* Col. Charles H. Alden, retired; Col. Calvin de Witt, Assistant Surgeon-General, professor of military medicine; Major John Van R. Hoff, surgeon, lecturer on the duties of medical officers in war and peace; Major William C. Borden, surgeon, professor of military surgery, *vice* Col. Forwood, designated as President of the faculty; Major Frederick P. Reynolds, surgeon, as instructor in hospital corps drill and first aid to wounded, *vice* Capt. George D. DeShon, relieved.

Washington State Medical Society.—The following officers were elected for 1902: President, Dr. J. W. Bean of Ellensburg; First Vice-President, Dr. F. H. Coe of Seattle; Second Vice-President, Dr. H. B. Luhn of Spokane; Secretary, Dr. A. H. Coe of Spokane; Treasurer, Dr. J. B. Eagleson of Seattle. Place of meeting, Tacoma.

Quarantine Against Cuba.—A strong disposition has been manifested by the local quarantine authorities of New York and by the Marine Hospital Service to remove the restrictions that have existed so long for persons arriving at this port from Cuba. It is admitted that no danger can arise from their admission if they remain in the northern part of the country. But the impossibility of controlling the movements of individuals when once set free has determined Dr. Doty to continue the present rules at least during the current year.

Obituary.—Dr. E. E. Waite, one of the best-known physicians of New Bedford, Mass., died suddenly in that city on June 20th. He had been in poor health. He was about forty-three years old.

Dr. George Hosmer Magness died at his home at White Plains, N. Y., June 25th, after a long illness. He was born in New York in 1851. Dr. Magness was graduated from the Bellevue Hospital Medical College with the class of 1876. In 1879 he removed to White Plains and built up a large and lucrative practice. He was the physician to the Home of Nazareth and to the Sisters of Divine Compassion.

Dr. James W. E. Roby of Brooklyn died in St. John's Hospital, Long Island City, N. Y., after undergoing an operation. Dr. Roby was thirty-eight years old. He was born in New York and after being graduated from the University of New York in 1887, began to practise in the Eastern District of Brooklyn, and was very successful.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, June 15, 1901.

THE GENERAL MEDICAL COUNCIL—ITS COMPOSITION—ITS PRESIDENT—ITS MEMBERS—THE DIRECT REPRESENTATIVES—SOME PROMINENT FIGURES—THE FUNCTIONS OF THE COUNCIL—ITS STRENGTH AND ITS WEAKNESS.

Our professional Parliament, the General Medical Council, is now in session. It meets twice a year, and as each member receives a fee of twenty-six dollars for each day of attendance, there is a natural tendency to the prolongation of sessions. The money is provided by the medical profession itself, each member of which has to pay twenty-five dollars to get his name placed on the *Medical Register* of which the Council is the official custodian. There is a pretty general feeling, however, that the profession does not get any value for its money. Our Medical Council is probably the most costly legislative body in existence, and one of the most loquacious. Every member feels it a duty which he owes to himself as well as his constituents to speak early and often, and as very few of them have anything to say that tends to edification, the oratory is for the most part *vox et præterea nihil.*

The Council is composed of elected representatives of the Royal College of Physicians and Surgeons in London, Edinburgh, and Dublin, of the Faculty of Physicians and Surgeons of Glasgow, of the Society of Apothecaries of London and of the Apothecaries' Hall of Ireland, and of the Universities of the United Kingdom, namely, Oxford, Cambridge, Durham, London, Victoria, Manchester, Birmingham, in England; Edinburgh, Aberdeen, Glasgow, St. Andrews, in Scotland; and the University of Dublin, and the Royal University of Ireland, in the Emerald Isle. Five members are nominated by the Crown, and five are direct representatives of the profession—three for England, and one each for Scotland and Ireland. The direct representatives are elected for five years by the votes of legally qualified members of the medical profession whose names are on the *Medical Register.* Their presence in the Council—which dates only some fourteen years back, whereas the Council has been in existence for over forty years—represents a victory of the democratic idea. The principle was bitterly opposed by the corporations and the universities who may be taken to represent the aristocracy in medical politics, but mainly owing to the efforts of the British Medical Association they were beaten. But, though perforce accepting the situation, they have never forgotten their defeat, and, like the French, they still dream of *la revanche.*

The Council is presided over by Sir William Turner, Professor of Anatomy in the University of Edinburgh, and a man whose high position in

the scientific world is shown by the fact that he was President of the British Association for the Advancement of Science in 1900. When the last President, Sir Richard Quain, departed this life there was a little difficulty about the election of a successor. Sir William Turner was the most prominent of the *papabili*, to borrow a phrase from the language of a conclave of a different kind; but it was objected that the fact of his living in Edinburgh would cause inconvenience. It was given out, however, that if elected to the presidential chair the Edinburgh professor would resign his chair as soon as he had served out the time required to entitle him to a pension. That time, it is understood, is past, but Sir William Turner seems to be in no hurry to vacate his chair which is estimated to be worth some twenty thousand dollars a year. He is not a Scot, but, like Richard Owen, a Lancastrian by birth. Nor is he a graduate of Edinburgh, having received his medical training at St. Bartholomew's Hospital and graduated at the University of London. He went to Edinburgh to be demonstrator of anatomy under John Goodsir and waited for his chair as long as Jacob did for Rachel. He is the dominant force in the Edinburgh Medical Faculty, and he brings a good deal of the dictatorial manner of the professor to the management of the General Medical Council.

Of the members of the Council the majority are professors, and consultants who know little and care less about the difficulties of the general practitioner. They live in a serene Olympus of academic dignity to which the cries of the doctors *à tout faire* struggling for their daily bread against the injustice of the law, the oppression of officials and the competition of quacks, reach only as a confused murmur mellowed by distance. The direct representatives are supposed to be champions of the general practitioners, but, in the first place, they are numerically a negligible quantity in the Council, and, moreover, they are of little weight personally. It must indeed be admitted that direct representation has so far not been a conspicuous success. This is due mainly to the indifference of the bulk of the profession which has had the result of leaving the elections practically in the hands of the rabble. Hence the profession in England finds itself represented in the General Medical Council by Mr. Victor Horsley who, deservedly eminent as he is in his proper scientific sphere, is in his medico-political aspect a blatant demagogue; by Mr. George Brown who may be described as in manner and tone as well as in purpose the equivalent of the labor representatives in the House of Commons; and Dr. J. G. Glover, a highly respectable family doctor who has for many years played the part of a kindly leading light to the *Lancet*. They are, like Brutus, honorable men, but with the exception of Dr. Glover they have no weight with the better classes of the profession of which they represent the baser elements. Scotland is represented by Dr. William Bruce of Dingwall, of whom, as of "poor Fred" in the epitaph, "there's nothing to be said"; and Ireland, by Sir William Thomson, a man of real distinction who has been President of the Irish College of Surgeons and who did right good work in South Africa as chief of the Irish Hospital in Pretoria. Of the direct representatives he best fulfils the idea of the character. He is a man of high intelligence who commands the respect of the whole profession, a stout but chivalrously fair fighter who can hold his own in debate without violence and scurrility; last but not least he is a gentleman. The direct representatives, few as they are, might do something if they held together. But they are incompatible elements, and the inevitable result is that they form an inert mass, liable to explosions akin to those of the "mad-volcanoes" spoken of by Carlyle.

Of the other members of the Council, the most active and able, is Dr. Donald MacAlister, the representative of the University of Cambridge. Dr. MacAlister had a university career of meteoric brilliancy and might have won the highest prizes at the bar; people were amazed, therefore, when he subsided into medicine. Bringing so exceptionally well-stored a memory and so thoroughly trained a mind as he did to the study of medicine, it might have been expected that he would have shed light into many dark places. But his scientific achievement has been infinitesimal, and as a practical physician he has hitherto failed to make any great reputation. Perhaps he has not exerted himself to do so. He has a versatile mind, and it might be said of him that he knows everything, even a little medicine. He holds a considerable position in his University, and in the Medical Council his clearness of head and grasp of business make him a power. He is the *bête noire* of Mr. Victor Horsley, the tempest of whose passion often dashes itself in foaming impotence against the rock of Dr. MacAlister's solid sense.

Among the other members the most interesting figures are Sir William Gairdner, formerly Professor of Medicine in the University of Glasgow, the very type of the philosophic physician, who can discourse with the copiousness of a full mind *de omni scibili* in medicine, and can bring the most multifarious knowledge and illustrations drawn with equal ease from Greek philosophers and American humorists to elucidate any given problem; and Sir Dyce Duckworth, the representative of the London College of Physicians, who should have lived in the days of full-bottomed wigs and gold-headed canes, and whose tone and manner seem to say,

> "I am Sir Oracle, and when I ope
> My mouth, let no dog bark!"

The Medical Council is entrusted by the State with the charge of medical education and registration, and, moreover, has certain disciplinary powers over members of the profession who are proved to be guilty of conduct "infamous in a professional respect." "Infamy" may attach to any deviation from the straight path of profes-

sional rectitude from advertising to abortion. An offence which smells with special rankness to the heaven of the Council is "covering," that is, an arrangement whereby an unqualified person practises medicine under the umbrella of one that is qualified. This device is still common, though the Council has done something toward its repression. It has abolished the unqualified assistant who used to have a recognized place in country practice, doing the cheap midwifery and the rough surgery, visiting the lower class patients and dispensing medicines, for a remuneration of five to six hundred dollars. He had from the employer's point of view, the advantage that he was cheap and that he could not start in opposition to his master. A few years ago a decree went forth that the employment of unqualified assistants would be treated as "infamous." It was undoubtedly a right thing to do in the interest both of the public and of the profession; but it was done with a want of consideration for the unfortunate persons thus suddenly turned adrift that smacked of the harshness of trade-unionism. The effect of the measure has been that practitioners have now to employ qualified labor at about double the price they paid for the unqualified, and they complain that they find the young graduates full of book learning, but in practice much less efficient than the humble drudges whom they have displaced.

The action of the Council in suppressing the unqualified assistant shows at once its strength and its weakness. It was able to prevent the registered practitioner from employing an unqualified assistant; but if the latter chose boldly to set up on his own account as a quack, the Council could do nothing to prevent him, as the only punishment it can inflict is removal from the *Medical Register*. In fact, the Council has no power to prosecute quacks, and this is one of the points in which reform is needed. But if the Council were to ask Parliament to grant it larger powers, it is not at all likely that it would get them. The little regard in which the Medical Council is held by the Legislature is shown by the snubs recently administered to it, as related in previous letters. There is a strong anti-medical feeling in the British Parliament at present, which is doubtless largely due to the criticisms which have been so freely made as to the treatment of the sick and wounded in South Africa. This matter will probably come up for discussion in the House of Commons at an early date, when it is to be hoped that one or other of the medical members will deal frankly and fully with Mr. Burdett-Coutts' charges. But in the meantime the feeling which these have roused would make it impossible to get Parliament to pass any bill tending to create a monopoly for the medical profession, or to increase the privileges which it already possesses. There would be a serious chance of any attempt in that direction leading to a relaxation of the existing law regulating medical practice, lax as that is, so that the last state of the profession would be worse than the first.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

PURE MILK—OMENTAL GANGRENE—PERFORATED GASTRIC ULCER—OVARIAN CYSTOMA—VARIOUS TYPES OF GASTRIC ULCER.

Crowley, at the Bradford Medico-Chirurgical Society, May 21, 1901, discussed the importance of a pure milk in communities and described two rather efficacious procedures. One system was working at St. Helen's and Liverpool and consisted briefly in humanizing and sterilizing selected cow's milk, bottling it in quantities for single feedings and delivering a day's supply at a time. The workings of the Manchester Pure Milk Supply Company were a little more thorough. The milk was accepted only from certain farms where the cows were frequently inspected, their hygiene looked after and frequent inoculations with tuberculin carried out. The farmers and their help are also under the control of the Company. If any infectious disease appears in their midst, the milk is refused from that farm until the case is cured and a safe interval of time has elapsed to make the milk healthful and not a possible source of infection. The loss to the farmer meanwhile is made up fully by the Company. The milk is taken to the Company just as soon as possible after being drawn, and there it is carefully strained, cooled and bottled, but not sterilized or humanized. Deliveries are made in daily or half-daily supplies. The great importance of securing pure milk can not be exaggerated. Perhaps in the long run it will be advisable to put the entire milk traffic in the hands of the Government.

J. B. Berry related the details of three celiotomies. The first was performed on a woman forty-three years old, multipara, who for some time (not definitely known) had suffered from abdominal swelling. During this process she became pregnant and was normally delivered of a full-term child. About fourteen days thereafter the swelling increased and tapping was necessary and had to be done several times. Upon finding the fluid each time more and more foul, a celiotomy was considered advisable, and revealed a walled-off cavity in which a large portion of the omentum was found gangrenous; this was separated quite easily and a large quantity of foul fluid evacuated. The cavity was washed out, drained freely and a wet outer dressing was applied. Slow but perfect recovery followed. The second patient was a seventeen-year-old girl who came under treatment for perforated gastric ulcer. The onset was hyperacute, while she was at work, with pain in the abdomen, faintness and vomiting. When first seen she had abdominal distention, thoracic breathing, pulse 98, temperature 100° F., pallor and shock. Twenty-nine hours after the beginning of the symptoms she underwent celiotomy. A small perforation admitting a probe was found in the lesser curvature of the stomach and closed by a double row of Lembert's sutures. The abdominal cavity was cleansed, but not

flushed. A complete recovery followed. In the third case, a woman had a large ovarian cystoma, which when emptied was found to have held seventeen and a half pints of turbid fluid. A straightforward recovery followed.

MR. HALL read a paper on the subject of gastric ulcer and its various types. Of these he thought there should be three, namely, the hyperacute or fulminating, the subacute or insidious, and the cases with localized abscess, the perigastric abscess of some writers. This classification is exactly parallel with that usually adopted to distinguish the forms of appendicitis. In the hyperacute cases no opportunity is given for any walling-off by the general peritoneum. In the subacute cases diagnosis is often very difficult and obscure. With localized abscess, we know the perforation has occurred and the peritoneal cavity has been protected, because the process has been slower. In the subacute cases a very safe rule to adopt will be that after careful physical examination and watching, if in doubt, explore. Of course, occasionally this will lead to operation when one might have been avoided, but the number of such will be far less than of those whose lives will be entirely saved by the procedure.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held at St. Paul, Minn., June 4-7, 1901.

SECTION ON MATERIA MEDICA, PHARMACY AND THERAPEUTICS.

Experimental Work in Intra-organic and Venous Injections in the Cure of Acute Organic Diseases.—The first paper was one on this subject by Dr. W. B. Coakley of Chicago, It dealt largely with saline solutions, which he contended had a very definite and useful place in practical therapeutics, although it was well known that exaggerated claims were made in regard to their efficiency in prolonging life and otherwise. Injections might be made into quite a number of organs without producing untoward symptoms, and the physiological experiments showed remarkable results in the way of restoring animation to animals in a state of collapse.

The Neglect of Valuable Therapeutic Measures.—This was the subject of a contribution by Dr. G. F. Butler of Chicago. Medicines and therapeutic agencies generally, he showed, were subject to fashion, and many useful remedial measures were neglected because of prejudice or the influence of commercial interests. Bloodletting, the use of normal salt solutions, counterirritation, complex prescriptions, hydrotherapy, massage, mechanotherapy, dietetics, suggestive therapeutics and physical culture had all received less attention than they deserved, in some cases because of the reaction against them caused by their having been carried too far, and the result was that a large field of natural therapeutics had been left to Faith Curists, Christian Scientists, Osteopaths and others, who had not hesitated to turn them to the greatest possible account.

Therapeutic Indications Presented by the Conditions of the Blood in Disease.—Dr. O. T. Osborne of New Haven, Conn., read a paper with this title. He contended that in the blood might often be found a key to the doubts that existed as to whether a patient would recover or not, and on this and other accounts he entered an earnest plea for greater attention to this department of investigation. He gave details of a number of interesting experiments he had made on dogs, and also reported the results obtained in different diseases on the human subject.

Chronic Myocarditis.—This paper by Dr. J. H. Musser of Philadelphia will appear in an early issue of the MEDICAL NEWS.

The Treatment of Obesity.—This subject was presented in a paper by Dr. Heinrich Stern of New York. He said that obesity was generally to be regarded as symptomatic, and therefore each case should be studied individually with the view of discovering its actual character and the causes that were responsible for it. Much harm was done by many of the methods in use for reducing corpulency.

The Treatment of Neurasthenia.—Dr. H. N. Moyer of Chicago in this paper said there was, he thought, a widespread misapprehension among members of the profession as to what constituted neurasthenia. It was frequently confounded with hysteria and hypochondria. There would be no objection to this confusion if the treatment was the same, but he believed that the failure to distinguish one from the other accounted for the large number of failures that took place in the treatment of neurasthenia. Correct diagnosis, therefore, in his opinion, was of primary importance. The distinctive feature of neurasthenia was the symptom of fatigue. If that symptom was absent it might be assumed that there was no neurasthenia. Hysteria never presented this symptom, and hypochondria was always founded on a pure delusion. A distinction ought also to be made between primary and secondary neurasthenia, and he would never determine that a case was primary until all possibility of its being secondary had been eliminated by process of exclusion. In primary neurasthenia, the rest cure was very effective, but in secondary neurasthenia, unless properly modified, it frequently did harm. The habits of life of every patient should be carefully regulated, and hydrotherapy ought never to be neglected. In regard to drugs, he differed from some of his associates by making strychnine his sheet anchor, and he also got good results from cannabis indica, the object of giving these drugs

being to produce a desired psychical state in the patient, but nothing more. It was a species of suggestion, and in the same connection he said the larger the dose of the doctor a neurasthenic got and the smaller the doses of medicines, the better it would be for him. He did not advise hypnosis and would not practise it, but the patient should be encouraged to think he was getting better. Cases of hysteria, he admitted, might develop into neurasthenia, and such cases were peculiarly difficult to deal with. He would not attempt to lay down a diet suitable for any group of cases, believing that each individual must be treated according to conditions and circumstances, but he placed a great deal of reliance on milk, using it when necessary in modified form.

Standardization and the Pharmacopœia.—Two papers were read on this subject, the first by Dr. C. F. Wahrer of Fort Madison, Iowa, being entitled "A Plea for More Uniformity and Strength in Our Armamentarium," while the second, by Dr. A. B. Lyons of Detroit, Mich., dealt with "The Standardization of Crude Drugs and Galenical Preparations." Dr. Wahrer said his views might be regarded as Utopian, but it was only by continually agitating this subject that they could hope to effect any improvement on the present unsatisfactory state of affairs. Physicians now knew more about the etiology of diseases and were better able to make a correct diagnosis than they were formerly; but he was afraid the question, Has therapeutics kept pace with advances in other branches of medical science? must be answered in the negative. This was not because the pharmacist had been idle, since many new remedies of undoubted value had been introduced. The misfortune was that they had no guarantee as to the quality of the drugs they made use of in fighting disease. Even the Pharmacopœia was open to criticism on the ground that it did not make adequate provision for the uniformity and strength of remedies that were officially recognized. This fact coupled with the cupidity and dishonesty of many manufacturers and the ignorant and careless making-up of prescriptions made the outlook for the sick man anything but cheerful. It was of little use for physicians to be able to make a correct diagnosis and know the proper remedy to prescribe, so long as they were ignorant of the quality of the drugs that were used in making up their prescriptions. He was far from wishing to reflect on manufacturing houses of high ethical standing, such as several he mentioned. It was well known, however, that there were other concerns which were continually forcing new remedies, often claiming to be specifics, on the attention of the profession. What was worse, the profession bought these drugs, and wrote testimonials in their favor, some of those who did so being professors in medical colleges with pretensions to high standing. No matter who they were, he thought all those who endorsed nostrums should be dismissed from their positions, and left free to devote all their time to the exploitation of the so-called remedies with which they had allowed their names to become associated. He thought that a body like the American Medical Association could do much toward bringing about a more satisfactory state of affairs, and he suggested that a committee be appointed for the purpose of trying to get the Pharmacopœia amended in such a way as to ensure the standardization of drugs and legislation passed by Congress to prevent adulteration.

Dr. Lyons, after making some complimentary remarks about the paper just read, gave illustrations of the extent to which vegetable drugs varied in medicinal activity, and argued that scientific medication required that preparations made from them be brought to some uniform standard of strength. Individual manufacturers supplied standardized preparations, but many of their assay methods were confessedly imperfect. Standardization by these methods was better than none, but it would be infinitely better if one set of standards was set by the Pharmacopœia. In the recent revision of that work, it was much to be regretted that standardization by physiological test had been ruled out.

Dr. C. S. N. Hallberg of Chicago, in discussing the papers, while in favor of drugs being standardized as far as possible, said it was difficult to apply any uniform rule so long as the active principle of certain drugs, such as aconite and digitalis, remained unclearly defined.

Dr. F. G. Wulling of Minneapolis, as a practical pharmacist, admitted the difficulties in the way of universal standardization, but at the same time contended that much might and ought to be done to bring about more uniformity than at present existed. Physicians, he thought, were equally to blame with pharmacists, and he suggested that they should make themselves more familiar with the contents of the Pharmacopœia and with materia medica generally, so as to be in a position to rely more on their own prescriptions and less on readymade preparations. The medical schools, in his opinion, ought to make the Pharmacopœia one of their text-books, and pay more attention to the teaching of materia medica and pharmacy.

The Chairman, as a member of the Committee charged with the revision of the Pharmacopœia, said he had always wished that the work could be changed in such a way as to make it interesting and practically useful to physicians. With a view to this he was in favor, on the one hand, of the exclusion of a great deal of matter that was now retained simply because the remedies it referred to were still used in certain parts of the country, though they had ceased to be used by the pro-

fession generally, and, on the other hand, he advocated the inclusion of information in regard to new remedies. It was the latter particularly that the physician wanted to know about, and reliable information should be furnished in regard to them irrespective of whether they had been standardized or not. They might be placed in an appendix, or otherwise distinguished from other drugs. What was important was that the Pharmacopœia should be a real encyclopedia of medical knowledge.

The Treatment of Pulmonary Tuberculosis.—A symposium on this subject was contributed to by Dr. S. E. Solly of Colorado Springs; Dr. Norman Bridges of Los Angeles, Cal.; Dr. Arnold C. Klebs of Chicago, and Dr. A. Burroughs of Asheville, N. C.

Indication for and Utility of Altitude Treatment.—Dr. Solly in his paper on this subject said that the climate of Colorado was intermediate between the cold that prevailed in the Alps and in some parts of Canada and the warm temperatures of New Mexico and Arizona. In considering the choice of places to which to send patients, it was necessary to take into account the general health, and the nature of the tuberculous disease, as well as the extent to which it had advanced. The cases that did best in high altitudes were primary cases, those that appeared like lightning from a clear sky without any obvious cause. He hoped the new sanitaria would lead to more scientific study of cases in their earlier stages and a better selection of the patients who were sent to different regions for climatic change.

The Adaptability of Southern California and Similar Climates to the Needs of Consumptives.—Dr. Bridges' claims for the region referred to were its relative dryness, the small rainfall, the large amount of sunshine, the fact that it had both high and low altitudes, and the mildness of the climate all the year round, which permitted patients to spend a large proportion of their time in the open air. Dr. Bridges also read a paper on "The Proper Management of the Tuberculous Lung," in which he maintained that the best course to pursue was to give the affected lung rest, and that this could be done most satisfactorily by means of external fixation.

Specific Therapeutics in Pulmonary Tuberculosis.—Dr. Klebs in his paper reviewed the culture products and serums used in the treatment of the disease, and also discussed the merits of pharmaceutic preparations of alleged specific value, the conclusion at which he arrived being that there was no drug possessed of specific virtues so far as tuberculosis was concerned, and that the best course for the general practitioner was to follow as far as possible the dietetic and hygienic treatment practised in the sanitoria.

Nineteen Years' Experience with Creosote.—Dr. Burroughs advised giving this drug in large doses and continuing it two years after all symptoms had disappeared. In his opinion no other medicine gave such good results in the treatment of tuberculosis.

Treatment of Pneumonia.—Dr. De Lancey Rochester read this paper in which he contended that, as the main factor in the disease was toxemia and no effective antitoxin had yet been discovered for counteracting its effects, medicines should be given for the purpose of eliminating the poison by natural means.

Gastric Disorders.—Dr. Boardman Reed of Philadelphia, opened a symposium on gastric disorders by reading a paper on "The Influence of Certain Common Remedies upon Gastric Functions." He showed that organs which were acting normally were liable to derangement by drug stimulation, and that a great deal of harm was done by the indiscriminate taking of medicines which were supposed to be harmless. Experiments he had made showed that hydrochloric acid and pepsin, when given separately, each tended to impair digestion, whereas given together they improved it.

The Treatment of Gastric Ulcer.—This was the subject of a paper by Dr. Gustav Fütterer of Chicago. There was always danger, he said, of ulceration of the stomach being followed by carcinoma. Nor was it always safe to assume that the disappearance of the symptoms meant that this danger had passed. Therefore the patient must be kept under observation for some time. As to treatment, he gave beef-juice properly prepared direct from the beef, and insisted on the patient getting absolute rest. Where there was any serious obstruction, he was in favor of an early gastro-enterostomy.

The Treatment of Hyperesthesia.—Dr. Charles G. Stockton of Buffalo said it was a mistake to regard hyperesthesia as a disease of the stomach, as it was in reality a derangement of the organism of which the stomach was the index. In reference to treatment, he advised the giving a slight diet of milk, farinaceous foods and eggs. Hydrotherapy was of great use and electricity could also be employed with advantage.

Dr. J. B. Herrick of Chicago complimented Dr. Fütterer on the useful work he was doing by investigating the character of gastric ulcers and ascertaining the different complications to which they gave rise. Clinical experience confirmed the results obtained experimentally, showing that cases in which the blood was deficient were the most likely to develop carcinoma. He agreed with Dr. Fütterer as to the advisability of early operation in the cases he had referred to, and he also agreed with him in regard to general treatment, except in this respect that he relied more on milk than on beef-juice, and when the patient was beginning to improve he added a little iron. Dr. Osborne observed that they could not be too careful in guarding against the common mistake of treating hyperesthesia as dyspep-

sia; Dr. McCoy of Duluth called attention to the special need there was in such cases to see that the food of the patients was properly prepared, and Dr. Boardman Reed said that the word "dyspepsia" had been much abused and it would be well if it were abolished altogether.

Organotherapy.—Papers under this head were read by Dr. Sydney Kuh of Chicago; Dr. John M. Dodson of Chicago, Dr. E. M. Houghton of Detroit, and Dr. Jokichi Takamine of New York. Before they were taken up, the Secretary read an abstract of a contribution which had been sent in by Dr. S. Solis-Cohen of Philadelphia on "The Theory and Practice of Organotherapy."

Dr. Kuh's contribution consisted of a report of cases in which acromegaly had been successfully treated with pituitary body, and Dr. Dodson's of a report of cases where the thymus extract had been effective in the treatment of Graves' disease.

Dr. Houghton described the pharmacology of the suprarenal gland and a method of assaying its products. He made special mention of adrenalin, the active principle of the suprarenal gland recently discovered by Takamine, and stated that it was 600, 800 or perhaps 1,000 times as strong as the ordinary aqueous solution of the gland.

Dr. Takamine gave a detailed account of the efforts that had been made by previous investigators to isolate the active principle, and of the partial success which had been obtained by several of them, notably Fürth and Abel. He gave full credit to these gentlemen and others for what they had done, but at the same time maintained that in adrenalin the active principle of the gland had for the first time been isolated in a free, basic, crystalline form. The physical and chemical properties of the product, the method in which it was prepared, its physiologic activity and the therapeutic uses to which it had been successfully put were also described by the speaker.

Dr. Victor C. Vaughan of Ann Arbor said Dr. Takamine was to be congratulated on having carried to a successful termination the efforts to solve a problem which had for so long a time engaged the attention of some of the most eminent men in this country and in Europe. There could be no doubt at all as to the utility of the extracts of different glands, and it was impossible to foresee what the next few years might develop in connection with organo and serum-therapy. Personally he had obtained extraordinary results from adrenalin in the treatment of long-standing hemorrhages.

Questions in regard to the properties of the drug having been put by several members of the Section, Dr. Vaughan said that he had not found that it had any untoward effects even when used daily for so long a period as three months. Dr. Houghton said that experiments were in progress with the view of deciding some points that were still unsettled. Dr. Takamine said he had confined himself to the chemical work of isolating the active principle; it was for physicians to test the drug and determine its therapeutic value.

A paper by Dr. B. T. Whitmore of New York on "America's Contribution to Medical Science" was read by title, which brought the literary part of the proceedings to a close.

Dr. George F. Butler of Chicago was elected Chairman of the Section for the ensuing year, and Dr. C. S. N. Hallberg of Chicago, Secretary.

BOOK REVIEWS.

Chronic Urethritis of Gonococcic Origin. By J. De Keersmaecker and J. Veerhoofen. Translated and Edited by Ludwig Weiss, M.D. William Wood and Company, New York, 1901.

It is always a difficult task to adapt any work treating upon highly specialized subjects to the needs of the general practitioner. In that respect, Dr. Weiss' excellent translation of De Keersmaecker and Veerhoofen's admirable work must fail. The reason is made plain in Oberländer's preface, *viz.*: "The study of urethroscopy is long and laborious, indeed. . . In the work which Drs. De Keersmaecker and Veerhoofen now present to the medical public, they have exposed with distinctness the principles of urethroscopy. Its study will thus become an almost easy matter for him who is willing to devote to it the necessary time, for he can only attain it by perseverance and after having attentively examined a large number of patients." Known for some years favorably to those who understand French, it is now presented in English, and must prove a valuable and desirable addition to the specialist's library. For the general practitioner, however, it is no more available now than in the original.

Of the contents, the chapter on the Anatomy of the Urethra is good, and that on the Pathology excellent; those dealing with urethroscopy bring that subject up to date, and are clear and complete; that upon Urethral Asepsis is very good, and that on Gonorrhea and Marriage rational and well worth reading. While the original chapters on treatment still contain much that is old, that by the editor on modern methods serves, in a measure, to remedy this defect. We regret, however, to see so little reference to the rôle of the prostate in the causation of chronic urethritis. A large percentage of all cases of gonorrhea show an involvement of the posterior urethra (in most of these this is equivalent to a gonorrheal prostatitis), and that these are among the most intractable should lead us to realize the enormous possibility of continuous re-infection of the urethra from this source. The book does not, therefore, by any means solve the problem of chronic gonorrheal urethritis.
